Lecturer in Physical Metallurgy at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (July 16).

Research Students (with a good degree in physics or mathematics) for experimental and/or theoretical work on a variety of problems including: properties of ionized gases, plasma physics, geophysical hydrodynamics, rock magnetism, study of the Earth's interior, and geomagnetism—The Administrative Assistant, Department of Physics, King's College (University of Durham), Newcastle upon Tyne 1 (July 16).

Assistant Lecturer (with a special interest in field ecology, pollen analysis or experimental taxonomy) in Botany—The Registrar, The University, Sheffield (July 18).

Research Fellow (graduate or person experienced in biochemistry) in the Department of Pharmacology, to work as part of a research team investigating various aspects of rheumatism and other diseases—The Secretary, The Welsh National School of Medicine, 34 Newport Road, Cardiff (July 18).

University Research Students in the Departments of Botany, Geography and Physics—The Registrar, The University, Hull (July 18).

Research Assistant (with an honours degree in geology, a good background in chemistry, and an interest or postgraduate experience in sedimentary studies) in the Department of Geology, to work on recent sediments—The Secretary, University College, Gower Street, London, W.C.1 (July 20).

Research Associate (graduate, with special qualifications in physical chemistry, physics or mineralogy and petrology) in the Department of Geology, for work upon hydrated alumino-silicate glasses and metals and for the development of apparatus for such work—Prof. F. W. Shotton, University of Birmingham, Edgbaston, Birmingham 15 (July 21).

Lecturer in the Department of Organic Chemistry, University of New England, Armidale, New South Wales, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, July 22).

Jeyes' Research Fellow (suitably qualified graduate) in the Biology Department, for research on biological or physico/chemical aspects of chemical soil sterilization—The Registrar, University College of North Staffordshire, Keele, Staffs (July 23).

Assistant Director of Graduate Studies in the Department of Physical Chemistry—The Registrar, The University, Leeds 2 (July 25).

Analytical Chemist (with a degree in chemistry or A.R.I.C.) at Ruakura Animal Research Station, New Zealand, to assist the officer in charge of the Biochemical Servicing Section of the Research Station, and to undertake non-routine analysis and to develop new methods—The High Commissioner for New Zealand, 415 Strand, London, W.C.2, quoting Ref. No. B.11/2/31 (July 30).

Assistant Lecturer in the Department of Metallurgy—The Registrar, The University, Manchester 13 (July 30).

Assistant Lecturer or Lecturer in Inorganic Chemistry—The Secretary, The Royal College of Science and Technology, Glasgow (July 30).

Chemist, Grade 3 (preferably M.Sc. in analytical and organic chemistry or biochemistry) in the National Biological Standards Laboratory, Canberra, for the development of methods for the analysis of drugs, etc.; checking of methods submitted by manufacturers; and the supervision of testing of drugs sold in Australia—The Director-General of Health, Department of Health, Canberra, Australia (July 30).

Head (with scientific training to graduate level, not necessarily in textile technology, but possibly in engineering or physics) of the Department of Textile Industries—The Principal, College of Technology, Belfast (July 30).

Lecturers in Mathematics, Physics, and Biology at the Royal University of Malta—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (July 30).

Physicist/Mathematician (graduate with a higher degree in physics or mathematics) at the New Zealand Oceanographic Institute, Department of Scientific and Industrial Research, Wellington, to carry out research in various branches of physical oceanography, for example, the dynamics of ocean systems; mixing processes; behaviour of water masses in boundary areas; or other aspects of the transfer of energy between atmosphere and ocean—The High Commissioner for New Zealand, 415 Strand, London, W.C.2, quoting Ref. No. B.11/21/29 (July 30).

Librarian (male graduate with a library qualification, and preferably a scientific background)—The Secretary, Royal Veterinary College (University of London), Royal College Street, London, N.W.1 (July 31).

Senior Lecturer in Physical Chemistry at the University of Natal, Pietermaritzburg, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, July 31).

Senior Lecturer in Physics at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (August 15).

Chair of Education in the University of the Witwatersrand, Johannesburg, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, August 31).

Lecturer in Archaeology—The Secretary of University Court, The University, Glasgow (August 31).

Lecturer/Senior Lecturer in Zoology; and Chair in Theoretical Physics at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, August 31).

Lecturer (with an honours degree in psychology together with acceptable qualifications and practical experience in clinical psychology) in Psychology at the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, August 31).

Departmental Demonstrator in Biochemistry—The Administrator, Department of Biochemistry, The University, South Parks Road, Oxford (September 15).

Assistant, Grade B (preferably with teaching experience) in the Department of Chemistry, Colour Chemistry and Dyeing, to teach general and inorganic chemistry to H.N.C. standard—The Principal, Huddersfield College of Technology, Huddersfield.

Assistant Lecturer (preferably with a Ph.D. in microbiology and research experience in this field) in the Department of Industrial Microbiology—Prof. E. Küster, Department of Industrial Microbiology, University College, Ardmore House, Stillorgan Road, Dublin.

Biochemical Assistant to assist with diabetic research—The Director, Medical Unit, Kings College Hospital Medical School, Denmark Hill, London, S.E.5.

Biochemist, Basic grade (graduate in chemistry or Associate or Graduate Member of the Royal Institute of Chemistry), in the Department of Pathology—The Group Secretary, Queen Elizabeth Hospital for Children, Hackney Road, London, E.2.

Hospital Physicist (with one or two years previous experience) in the Department of Pathology, for radioisotope work covering a wide field—The Group Secretary, Queen Elizabeth Hospital for Children, Hackney Road, London, E.2.

Laboratory Technician (male or female, A.I.M.L.T., and preferably with experience in blood transfusion work) in the Uganda Government Medical Department—The Crown Agents, 4 Millbank, London, S.W.1, quoting Ref. M.3C/52442/NF.

Lecturer or Assistant Lecturer (Grade E) in the Department of Applied Physics—The Principal, Welsh College of Advanced Technology, Cathays Park, Cardiff.

Lecturer or Assistant Lecturer in Physics at the University College of the West Indies—The Secretary, Inter-university Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1.

Mathematical Physicists (capable of leading teams in theoretical research, and proved ability to do effective work in novel fields)—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berkshire, quoting Ref. 2696/34.

Postdoctoral Fellow in Organic Chemistry, to work in collaboration with Dr. E. J. Forbes on the photochemistry of tropolones and related topics—The Deputy Registrar, The University, Edgbaston, Birmingham 15.

Postdoctorate Fellow in the Chemistry Department, for work on infra-red emission from gaseous chemical reactions—Prof. J. C. Polanyi, Department of Chemistry, University of Toronto, Toronto, Ontario, Canada.

Professor or Associate Professor of Mathematical Physics; and Assistant Professors (2) in Applied Mathematics or Mathematical Physics at the Royal Military College of Canada—Dept. 2009, National Employment Service of Canada, 61 Green Street, London, W.1.

Research Assistant (recently qualified organic chemist or biochemist) to undertake work on a chemical problem connected with cancer research—Professor Green, Department of Experimental Pathology and Cancer Research, The University, Leeds 2.

Research Assistant (suitably qualified graduate) in Botany and Zoology, to work on problems in cyto-chemistry, entomology, animal ecology or freshwater biology—Dr. J. K. Sparing, Head of the Department of Botany and Zoology, Sir John Cass College, Jewry Street, London, E.C.3.

SCIENTIFIC OF (with a science degree, and pre-
ferably a special r blood transfusion techniques)
IN THE LABORAT H LONDON TRANSFUSION CENTRE,
for duties consist ical laboratory work and research
and also to take istration of the department—The
Director, South I n Centre, Stanley Road, Sutton,
Surrey.

SENIOR LECTURE ATHEMATICS, and a LECTURER IN
MATHEMATICS at I , The University College of Sierra
Leone—The Secre ity Council for Higher Education
Overseas, 29 Wob m, W.C.1.

TECHNICAL OFF), with a degree in mathematics,
or an honours deg with a mathematical background)
IN THE SURVEY vernment of Kenya, for survey
computations and / plans—The Director of Recruit-
ment, Colonial O l, quoting BCD.103/7/09/NF.

BRITISH DEFENCE RESEARCH AND DEVELOPMENT

THE pattern of British defence policy can seldom have been so quickly transformed as that set forth in the Report on Defence* issued on February 17. Claiming that during the third year of the Five-year Plan for Defence the Government's broad defence policy had undergone no major change, the recent White Paper on Defence admitted that it might be decided not to rely exclusively on fixed-site missiles as the successor to the medium bomber armed with the stand-off powered bomb. Accordingly, the possibilities of mobile launches, whether aircraft or submarines, for long-range delivery of nuclear warheads are being investigated.

In opening a debate on this White Paper on February 29, the Minister of Defence, Mr. Harold Watkinson, paid a tribute to the work of his Chief Scientific Adviser and his team of experts, and referred to the immense technological changes taking place in defence by new methods of computation and production, which are enabling problems to be solved which could not have been even formulated with precision a few years ago. But, apart from suggesting that we might be led to give greater emphasis to mobility and flexibility, he said nothing further to foreshadow his announcement on April 13 that the Government has decided to discontinue the development of *Blue Streak* as a military weapon. Indeed, on February 29, he had endorsed what Mr. Sandys, his predecessor as Minister of Defence, had said in the Defence debate in February 1959, that *Blue Streak* was going ahead, but that we would watch the progress of other developments in the United States and elsewhere, and that with the rapid advances of science, which are constantly upsetting earlier assessments, strategic plans and weapon programmes can never be regarded as permanent or inevitable. Specifically, he said that what we have learned from the development of *Blue Streak* has been of some help to the Americans, and that we have already learned much both in the technique of propulsion and in the design of the very complicated guidance and computation systems that are the necessary concomitant of any ballistic missile. Final decisions on the balance Britain should hold between fixed-site missiles and mobile launchers, Mr. Watkinson said then, had not been taken, and he would like much more information about *Skybolt*, a ballistic missile of considerable range which could be launched from an aircraft, and also about the future development of *Polaris*, a solid-fuel rocket generally designed for a mobile role, and he was also having examined more closely the defence aspects of space research, at which he thought we need to look very carefully. Lord Hailsham, too, in the House of Lords debate on March 9, had been equally emphatic that British policies must be constantly open to revision, and equally he stressed the fact that the nuclear weapon, though in his view indispensable, is no more than one of the factors that make up defence policy. Of the £1,600 million covered by the Defence Estimates, no more than about 20 per cent could be attributed to the nuclear deterrent and its defence, and 10 per cent to the deterrent itself. About 14 per cent was spent on research and development, and in this connexion Lord Hailsham affirmed that we must be ruthless in our determination to scrap anything which cannot be justified, and resolute to support whatever is necessary by way of research and development.

Little was, in fact, said about defence research and development, though, in the House of Commons, Mr. J. Grimond suggested that, taking research into account, the whole of the nuclear weapon programme of research and development would represent 15–20 per cent, and Sir Alexander Spearman asserted that on research alone the United States is spending more than double our defence budget. Mr. Watkinson asserted, however, that it is much nearer 15 per cent, but on April 13 he admitted that the cost of completing the *Blue Streak* project would be between £500 and £600 million. None of the £95 million already spent would be wasted if it was decided to go ahead with *Blue Streak* as a launcher for a space satellite; but the admitted costs for *Seaslug*, *Thunderbird* and *Firestreak* bring the estimated missile bill to some £205 million, leaving out of account the stand-off weapon of the Royal Air Force designed to be launched outside the range of the enemy's defences, for which no figures are available in the Auditor-General's recent analysis. Incidentally, Sir Frederick Brundrett, former chief scientist to the Ministry of Defence, who still considers that *Blue Streak* could provide at least until 1970 an effective independent British contribution to the Western deterrent, has also supported the submarine-launched missile in preference to an air-launched missile.

There are two points made in these Defence debates that are of particular interest to the scientist and technologist. First, the inordinate time taken to plan, develop and produce the more complicated and technical weapons of itself increases the expense, and Lieut.-Commander S. L. C. Maydon suggested that it might be worth while to set up a small committee of experts consisting of an experienced industrialist, a senior Service officer of up-to-date ideas and a man experienced in time-and-motion study to look into the possibility of reducing the time taken to design and build a ship, aircraft, tank or other equipment. Commander Maydon did not suggest that this would lead to more than comparatively minor savings or short cuts, but in view of the magnitude of the expenditure involved they could be well worth while.

the Report on Basic Research in the Navy by the United States Naval Research Advisory Committee*. Reference was made to the latter report in *Nature* of February 27, but was confined to only one interesting aspect of the inquiry—the possibility of measuring the effectiveness of research and development—and by no means indicates the extent of the contribution which the two volumes of this report could make to the public understanding of the interrelations of defence and civil research. Besides this model for the discovery and application of knowledge, which is the major appendix constituting Vol. 2, together with some man-power studies bearing on research and development, there is a chronological list of naval technical developments to illustrate the impact of science and technology on the evolution of the United States Navy and a brief bibliography. The first volume comprises the conclusions and recommendations of the Naval Research Advisory Committee and the report to that Committee on basic research in the U.S. Navy, prepared by A. D. Little, Inc., setting forth the nature of basic research and its relation to military ends.

It is these conclusions and recommendations that deserve to be noted at the present moment when misgivings are being expressed about the soundness of the scientific and technical advice being tendered on defence matters in Britain, and the adequacy of existing arrangements to ensure that such advice is timely and effective. The report points out that in the past basic research has transformed naval strategy and tactics by its findings in such fields as radar, inertial guidance, missile propulsion and nuclear propulsion, and suggests that the United States Navy should support enough research in each area of interest to provide effective coupling and judgment for its own needs. That may well be too much a counsel of perfection for Britain, with her more limited resources; but it is assuredly true for her also that each Service Department should be competent and alert to appreciate the scientific findings of its own or other workers, and the significance of such findings to its own responsibilities and functions.

The Naval Research Advisory Committee considers that the basic research effort in the United States Navy should be about doubled to restore the former relation of basic research to the total research and development effort, and this would bring that effort nearer to the 16 per cent now current in progressive scientific and engineering industries. The report does not attempt to detail the programme proper, but it suggests that the Office of Naval Research should prepare detailed programmes in some seventeen fields of scientific work related to the missions of the Navy. Some of these are obvious prime or major responsibilities; others require effective co-ordination with what is being done elsewhere. The fields specifically listed are: physics; astronautics and aeronautical engineering; material sciences; electronics; mechanics; medical sciences; biology and biological sciences; oceanography; chemistry; geography; psychology; operational research; meteorology; astronomy and astrophysics; mathematics; combustion; earth physics.

---

* U.S. Department of Defense. Department of the Navy: Naval Research Advisory Committee. Basic Research in the Navy: Report to the Secretary of the Navy by the Naval Research Advisory Committee. Report prepared by Arthur D. Little, Inc. Vol. 1: Pp. xi+69. Vol. 2: Pp. i+102. (Washington, D.C.: Department of the Navy, 1959.)

It is not suggested, of course, that the U.S. Navy should attempt to cover all aspects of these fields, and it is recognized that, in planning research, use should be made of scientists and administrators from the universities and industry. Moreover, when a total programme has been prepared, a critical review is needed, to ensure that the total cost is within the budget. Although the report says comparatively little about the co-ordination of naval research in the United States with that of basic research for the other Services, apart from the admirably chosen examples of the way in which advances in basic science and technology have affected naval tactics and operations, these proposals demonstrate the dependence of naval efficiency on an adequate national effort in research and development, and the existence of appropriate means of ensuring that that effort is adequate and that its results are effectively communicated.

It is here that Prof. Blackett's lecture is so pertinent. He gives us much more than a thoughtful study of the influence of one man of outstanding ability. He indicates the qualities that are desirable in those, both within the Services and outside, who are called upon to decide on the programmes of research and the resources to be allocated to them. His lecture, too, is highly suggestive as to the conditions which favour the throwing up of such men and establishing co-operation and confidence between the Services and scientists and technologists. His comments both on the Defence Research Policy Committee and the Advisory Council on Scientific Policy, as well as on the importance of the Institute for Strategic Studies are also constructive, and it should be noted that Prof. Blackett considers that the Defence Research Policy Committee has proved a more effective instrument than the Advisory Council on Scientific Policy.

Whether, in fact, the Defence Research Policy Committee is still sufficient may well merit re-examination. It has been suggested that the system by which each of the three Services has a chief scientific adviser with a staff of scientists, and the Ministry of Defence a chief scientific adviser to the Government is insufficient, and that there should also be a scientific member of each of the boards or councils of the three Services and of the Chiefs of Staffs Committee. That seems, however, unlikely to be effective unless the other members of those bodies are capable of assessing the significance of scientific advice, and the solution of the problem may well turn on that of men and training as Prof. Blackett's lecture indicates, and the finding of men possessing the qualities which command respect from the Services and scientists alike and capable of understanding the issues involved and inspiring the co-operation required. Mr. F. J. Bellenger, in the debate on the Army Estimates on March 9, when urging the importance of senior officers in all the Services being equipped with scientific knowledge and training, rather implied that this is not yet generally the case.

Given those conditions—appropriate organization, an adequate supply of men of the high qualities, vision and sound judgment, as well as conditions which favour the informal contacts and discussions to which Admiral Hallett referred, with which any formal organization should be supported—it will still be difficult enough to reach wise decisions on strategy and tactics. Apart from the danger that political prejudice or uninformed judgments may take control, there is always the risk in this rapidly changing and complex technological world that matters of tactics may determine strategy, and even the policy behind strategy, and here such books as Alastair Buchan's "NATO in the 1960's: The Implications of Interdependence"* are valuable.

In this field and at this stage the scientific and technical aspects cannot be sharply separated from the political. All that the scientist or technologist as such can hope to do is to see that the former aspects are adequately and effectively presented, and that their implications are grasped. If as *The Economist* has suggested, the key question of our time is where in the civil field the investment of extra resources in research might pay the best dividends, or what is the scale of research and development it might be worth while devoting to particular industries or sectors of the economy, the question of priorities is equally vital in defence. Indeed, it is the factor which should decide what we can afford to spend on defence; and apart from any risk that our research effort generally may be affected by considerations of prestige rather than sound economy, the suggestion that too much effort has been put into nuclear energy, electronics and aircraft, and too little into machine tools and shipbuilding, should not be dismissed without examination.

Mr. Buchan's book is primarily an attempt to grapple with the problems which confront the North Atlantic Treaty Organization in its second decade. He seeks first to define those requirements and then examines the adequacy of existing arrangements and resources to meet those demands. In effect, he considers that the channelling of an increasing proportion of our resources into nuclear weapons has left us incapable of defending local or secondary interests by traditional methods and he maintains that conventional forces are not outmoded. He questions also the wisdom and utility of the policy which has given Britain an independent force with nuclear bombs and bombers. Deterrence, he argues, has replaced defence, and he would transfer to NATO the British independent nuclear force.

That view is not accepted by Prof. Blackett, who, in a comment appended to the book, rejects the idea of creating a European system of intermediate-range

be done by making our conventional forces ineffective.

Lord Shackleton, however, took a very contrary view, in referring in a House of Lords debate on May 3 to the decision to abandon the development of *Blue Streak* as a missile. Quoting Prof. W. R. Hawthorne's opinion, expressed at a meeting of the Parliamentary and Scientific Committee, that if we shut out a new technology or let it filter slowly through from some foreign country, we should reduce the resources of skill and experience upon which our designers can draw, Lord Shackleton was urging not so much development of the independent deterrent as of a space-research programme offering prospects of a major scientific and economic development. Lord Hailsham had said in the earlier debate on defence on March 9 that he was convinced that humanity must find a means of abolishing or controlling nuclear and other weapons, or sooner or later disaster would occur; but that the abolition of nuclear weapons must be considered in the context of general disarmament. On May 3 he pointed out that if by 'independent deterrent' we meant one of such power that by the use of it alone we could hope to engage one of the Great Powers on our own with hope of victory, in his judgment Britain has never had and is unlikely to have such deterrent. All we have at present is a significant part of the Western deterrent under our control.

Apart from linking this question of a nuclear deterrent with that of disarmament in general, Lord Hailsham's speech on May 3 is of interest for what he said about the close balance of the arguments both to start the development of *Blue Streak* as a missile and to stop it, the conditions of Anglo-American co-operation and his reply to Lord Shackleton on space research. Lord Hailsham said that we are now spending about 8 per cent of our gross national product on foreign aid or on defence, compared with 11 per cent by the United States. The question of space research, he said, should be approached with great caution, as we must be selective in what novel technologies we can develop, and if *Blue Streak* is to be developed for that purpose it would be a first consideration whether this might not be a co-operative enterprise. The decision to undertake space research, however, must be based on careful appreciation of the scientific and technological factors involved, and while Lord Hailsham agreed that space research may have important secondary effects on the rate of progress in such fields as electronics, metallurgy and telecommunications, Lord Hailsham was clearly averse to making any switch in our fully extended scientific effort without due forethought.

The harmonious working of the present system of defence research and development in Britain depends largely on the tact, efficiency and self-effacement of the staff of the Ministry of Defence. They create, indeed, an atmosphere and tradition for successful inter-Service negotiation and co-operation. What is clearly also required is something of the same atmosphere and tradition between defence and civil research, such as Sir Henry Tizard was so successful in inspiring. The Minister for Science has undoubtedly a large part to play, and the Government's ultimate decisions regarding *Blue Streak* and space research may well indicate also how effective the arrangements for co-ordinating civil and defence research and development are likely to be, now that the new Ministry has been established, and whether it is not imperative to re-examine urgently the functioning and relations of both the Defence Research Policy Committee and the Advisory Council on Scientific Policy. If the debates on the White Paper on Defence, on the Service Estimates and on the *Blue Streak* missile have done nothing else, they have demonstrated the need for informed and impartial discussion, especially in scientific and technical circles; and at the same time they have shown up the absence of much of the information upon which any such discussion must be based if it is to be worth while.

CONTROL OF SCIENTIFIC RESEARCH IN THE UNITED STATES

Science and State Government

A Study of the Scientific Activities of State Government Agencies in Six States. By Dr. Frederic N. Cleaveland. Pp. xvi+161. (Chapel Hill, N.C.: University of North Carolina Press; London: Oxford University Press, 1959. Published for the Institute for Research in Social Science.) 3.50 dollars; 28*s*. net.

To some extent, Dr. Cleaveland's study of the scientific activities of State Government Agencies in the six States of California, Connecticut, New Mexico, New York, North Carolina and Wisconsin is a complement of D. K. Price's "Government and Science", which was concerned essentially with the scientific activities of the Federal Government and the interaction of science and public policy. Dr. Cleaveland scarcely enters into those larger issues. For the British reader his book lacks the outstanding interest of Mr. Price's study; however, some at least of the experience he surveys bears on problems encountered in Great Britain. There is no clear parallel in British experience to the State system, though strong pressure has at times been exerted for the establishment by the Department of Scientific and Industrial Research of local research stations for Scotland or Wales. The six States covered by this report are already expending £1–15 million a year on scientific activities as compared with an estimate for 1960–61 of some £12·7 million for the Department of Scientific and Industrial Research, £5 million for the Agricultural Research Council, £4 million for the Medical Research Council and more than £65 million for universities and colleges, etc.

No local scientific expenditure of such magnitude is to be found in Great Britain, and although these sums are small against the Federal Government expenditure on scientific activities of approaching £1,000 million, they raise, as Dr. Cleaveland shows, important problems of co-ordination and balance. There are, for example, considerable variations in the expenditure in particular fields as between the six States; in agriculture it varied from a fifth to two-thirds of the State expenditure in that field, whereas in health, education and welfare it was usually less than 0·5 per cent, and only as much as 1 per cent in one State. In the development of resources and public works, it was 1 per cent or less in four of the States, but in the semi-arid States of California and New Mexico, with major problems of physical resources and significant mineral resources the figure was 1·7 and 2·8 per cent, respectively. Again, four States invested 3–4 per cent of the total expenditure on the State university in scientific activities, chiefly research, and in Wisconsin and in California this figure ran to 5·8 and 8·5 per cent, respectively, probably because of the extent to which these two States rely upon their universities for the provision of major research activities. In California, indeed, more than 92 per cent of the expenditure on scientific activities was on research, compared with 70–77·5 per cent in the remaining States. Expenditure on basic research in 1954 varied from less than 0·5 million dollars in New Mexico to 10·5 million dollars in California, or 16 per cent and 39·5 per cent of the budget for scientific activity compared with 25–33 per cent in the remaining four States, and some 40–50 per cent on applied research (70 per cent in New Mexico and 60 per cent in California). The study also indicated that State research efforts are heavily weighted in the direction of the biological sciences, physical sciences receiving only 20–30 per cent of research funds in four of the States, only 5 per cent in New York but nearly 50 per cent in New Mexico, compared with 87 per cent from the Federal Government's research and development expenditure.

There was some State expenditure on related scientific activities, such as scientific information, the training of scientific man-power and the planning and administration of research, and Dr Cleaveland found that the allocation of scientific man-power was in accordance with the picture of scientific activity provided by the analysis of expenditure, and his analysis of the role of the State university suggests that in some measure the idea of a regional university has found favour. Problems of administration, inter-government relations and the position of the scientist under the State Governments are also discussed, and in his concluding chapter Dr. Cleaveland presents his conclusions and points to certain weaknesses revealed by his study. As might be expected, one is a lack of balance in scientific activity, and another the limited use made of research as a means of aiding policy. Nevertheless, he suggests that scientific activity at the State-level is already assisting the practice of State Government in various ways, but it would appear that for the more effective utilization of scientific as well as national resources further assistance from Federal institutions such as the National Science Foundation, which has issued its own report on this survey, is needed. Of particular interest also is the picture given of the State universities and the pattern of their dependence on Federal and on State support; but the issues involved are not really discussed though they will largely determine the success or failure of the present effort to expand scientific and technological education in the United States. To the British reader some such examination of the factual data assembled in this survey would have been welcome, especially as here and there Dr. Cleaveland shows that he is fully competent to make such an appraisal.

showing signs of hasty preparation, being marred by several misprints, these appendixes should prove of enormous help in providing the necessary scientific background for the 'non-technical' reader; and at least one electrochemist found them to constitute rather more than a refresher course. Perhaps, however, we could have had a little more about exchange currents and the differences between the hydrogen and oxygen reactions in this respect, in view of their important bearing on over-potential in corrosion and electroplating systems.

As well as re-arranging his material, the author has slightly expanded it (what was 800 pages in the 1948 edition of "Metallic Corrosion, Passivity and Protection" is now 940 pages), in particular as regards the conjoint action of stress and corrosion, hydrogen cracking and the corrosion of buried metals. Four chapters are devoted to oxidation, six to electrochemical corrosion, three to a consideration of practical environments (for example, boilers), three to conjoint effects (stress-corrosion, corrosion fatigue and fretting corrosion), three to corrosion protection (coatings and inhibitors) and there are two chapters on testing methods and the statistical treatment of data.

One could not wish for a more comprehensive or well-written book, and, despite the threefold increase in price since "Metallic Corrosion, Passivity and Protection" in 1948, there can be no doubt that it constitutes a 'must' for anyone hoping to keep abreast of corrosion science and practice.

J. M. WEST

PROGRESS IN NUCLEAR SCIENCE

Annual Review of Nuclear Science
Vol. 9. Edited by Emilio Segrè and Leonard I. Schiff, in association with Gerhart Friedlander and Walter E. Meyerhof. Pp. vii+625. (Palo Alto, Calif.: Annual Reviews, Inc., 1959. Published in co-operation with the National Research Council of the National Academy of Sciences.) 7 dollars.

THE ninth volume of this series maintains the high standard set in previous years. Wilkinson reviews the recent, and on the whole satisfactory, developments in the theoretical interpretation of nuclear photodisintegration experiments. The high-energy field is again prominent. Chew contributes a clear and concise discussion of the recent field theoretical approach to pion-nucleon interactions through dispersion relations and 'polology'. This is a difficult subject but of great importance for the understanding of high-energy interactions. High-energy nuclear reactions are discussed by Miller and Hudis. This embraces spallation, fragmentation and fission at 100 MeV. or more and includes a detailed compilation. Okun' (Moscow) discusses the weak interactions, that is the decay properties of the new strange particles. This is the portion of high-energy physics which is changing most rapidly. Konopinski contributes a most useful review of β-decay theory which is timely now that the violation of parity 'revolution' is complete. It complements Okun's article admirably.

Four reviews of very general interest are nuclear fission by Halpern, nuclear electronics by Kendall, plasma and fusion research by Post and fast reactors by Koch and Paxton. In all these subjects many interesting developments can be reported. An article on the economics of nuclear power by Lane is unfortunately only pertinent to the United States and so is of limited interest.

Two chemical contributions, technetium and astatine chemistry by Anders and solvent extraction by Freiser and Morrison record facts and techniques hitherto scattered through project reports. Three radiobiological articles as usual complete the volume: vertebrate radiobiology (embryology) by Rugh, biochemical effects of radiation by Ord and Stocken, and cellular radiobiology by Atwood. These demonstrate the continuing advance in this broad field.

E. B. PAUL

MASS, LENGTH AND TIME

An Introduction to the Physics of Mass, Length and Time

By Prof. Norman Feather. (Science and Mathematics Texts, No. 1.) Pp. ix+358. (Edinburgh: At the University Press, 1959. Distributed by Thomas Nelson and Sons, Ltd.) 18s. net.

THE early part of this excellent book deals with the history and philosophy of fundamental measurement, together with the practical problems of defining, preserving and reproducing standards. It is a fascinating story, told with scholarship and skill. The rest presents the usual matter of a course of Advanced Level General Certificate of Education standard in mechanics and general physics in an unpretentious and thoughtfully penetrating way.

Prof. Feather has, as he puts it, "disdained to use the calculus". This is not really hauteur, but a means of enforcing a pace of slow and careful reading; the modern student is all too fluent, and can use it slickly without thinking. At the same time, it can be argued that the moment you introduce the concepts of velocity and acceleration, draw a continuous graph, or use moment of inertia or impulse, you are really using the calculus, though not its notation. You do not remove the tune from a piece of music by writing it in tonic sol-fa. The author does unbend a little in the last chapter, in fact. But if he had not himself directed attention to this point specially, it would not have called for comment.

Newtonian mechanics, and what John Cox called "the winning of the principles", are clearly explained, with emphasis on the importance of the third law. A whole chapter is devoted to potential energy, which is really a much deeper matter than the usual elementary books suggest. Gravitation is treated historically, starting with the genesis of Newton's law and ending with the design problems of apparatus of the type devised by Cavendish. For the rest, the discussion of the struggles of Archimedes with the law of the lever, and that of surface tension in terms of interfacial energy and molecular attraction, are among the many stimulating treatments.

The general outlook of the book is more like that of "Norman Campbell" or "Pearson" or "Pohl" than that of the ordinary text-book, though teachers of sixth-form physics would do well to consider its possibilities for class use, and it would certainly be a valuable book for students to read. It puts the inquiring approach of the scientist before the factual knowledge of the examinee. The liveliness and effortless dry humour, fortified by a wealth of historical detail, make it very pleasant to read, and the publishers have produced it most attractively.

G. R. NOAKES

SPOTTING KETOSTEROIDS

Oxosteroids

The Use of Phenolic Hydrazides for Detection, Characterization and Estimation. By Bernard Camber. Pp. viii+79. (London: H. K. Lewis and Co., Ltd., 1960.) 12s. 6d. net.

WHAT we used to call 'ketosteroids' can usually be estimated by some modification of the Zimmerman reaction, and the colours given by different ketosteroids with alkali and *m*-dinitrobenzene have long been used in 'spotting' on paper chromatograms and in the test-tube as a rough guide to the position of the keto group in the steroid molecule in unidentified substances.

Dr. Camber is a medically trained man with an interest in chemistry. His little book is an account of his search to find a hydrazine derivative which would condense with known physiologically important ketosteroids to give hydrazones which could be used to provide a quantitative method replacing the Zimmerman procedure, to identify individual ketosteroids as spots after chromatography on paper and in the histology of steroid-containing tissue. After forty-one pages, he arrives at salicyclic acid hydrazide (salicoyl hydrazine), which readily gives, with ketosteroids, hydrazones that can be used for these purposes. The early part of the book has a short account of some methods used for steroid estimations and also details of Dr. Camber's less-useful derivatives of hydrazine. His finally chosen reagent is valuable, although the quantitative methods have not received exhaustive testing with urines and only preliminary histological work has been done. 'Spotting' on paper chromatograms is, however, well developed, giving useful information about steroids separated. The author is an ingenious experimenter, as is shown, for example, by his technique of spot testing in 'Cellophane'. It is also clear that he has enjoyed doing and expounding his work. He is perfectly frank in not pretending that his reagent is perfect for the purposes suggested: he gives details and obviously would prefer those interested to try it for themselves.

Workers in this field will be willing to buy this book for the 'know-how' which it contains. Full experimental details are given for all methods, qualitative and quantitative, recommended, including the preparation of a sufficiently pure sample of salicyclic acid hydrazide.

G. A. D. HASLEWOOD

STUDIES IN MARINE PHYSICS

The Gulf Stream

A Physical and Dynamical Description. By Henry Stommel. Pp. xiii+202. (Berkeley and Los Angeles: University of California Press; London: Cambridge University Press, 1958.) 45s. net.

IN Europe, at least, marine biologists vastly outnumber marine physicists, and one of the things that has prevented physicists from becoming interested in the oceans is the difficulty of finding concise accounts of the problems written in the precise terms to which they are accustomed when dealing with modern science. Dr. Stommel is one of the leaders of a strong theoretical group in the eastern United States, who has spent many years studying the Gulf Stream, and his book gives a clear and

charge of raspberry and
East Malling since 1954,
t up a useful abstracted
Rubus. For the specialist
to be complete, but also
y of papers in foreign
urnals, must be sufficiently

detailed to be of value. The authors have only partially succeeded in this last respect. The bibliography is incomplete, and several recent important papers by British authors on the cytology and genetics of British forms of *Rubus* are unfortunately listed by title only. Some of the individual abstracts are good, for example, the salient features of the 76-page paper of Fassett on mass collections are condensed into ten lines. Some other abstracts appear to be condensations of earlier abstracts, and one wonders if these have been verified: for example, work by Downick is wrongly attributed to LaCour. Bibliographical errors are few: Zinno should read Jinno.

One disadvantage of a bibliography is that a newcomer is not readily able to assess the relative merits of the individual papers, and here the compilers have not helped. Although some papers, such as Spinks's on black currant breeding at Long Ashton, are fully abstracted, the length of an abstract provides little indication of a paper's scientific merits. This book would, therefore, have benefited from sieving. Some of the now worthless earlier papers could have been omitted, and the space used to provide the authors' comments on the more important ones.

A most unfortunate decision has been to mix the references of *Ribes* with *Rubus*. Two separate bibliographies with their own indices would have been an advantage, especially when surveying previous work on each genus, and in using the subject index.

Two appendixes are provided. That of a gene list for *Rubus* concerns only raspberry, but several genes are known in blackberry; it is perhaps unfortunate that the symbol *A* is given to *Amphorophora* resistance, as this had already been assigned to autumn flowering (not listed). Appendix II gives two linkage groups, of especial interest for until now it had seemed that all the tested genes in *Rubus* lie on one chromosome, and the remaining six chromosomes were possibly inert. No gene list is given for *Ribes*, although data are available in the omitted "Genetics of Garden Plants" (Crane and Lawrence). No list of chromosome numbers is provided, which would have been useful as there is no reference to Darlington and Wylie's "Chromosome Atlas".

A graph, calculated from the bibliography, clearly shows that breeders have been, and will be, more interested in raspberries, blackberries and kindred fruits, than in gooseberries and currants. Indeed, research with *Rubus* now considerably outstrips that for *Ribes*. This is partly because *Rubus* affords more genetically versatile experimental material, and partly from lack of interest in *Ribes* in North America, where *Ribes* cultivation is banned. Yet the considerable demand for black currant juice abroad provides the basis for the present policy at Mylnefield to breed high-yielding, uniform, early ripening varieties, to increase the acreage in the soft-fruit areas of the East of Scotland.

This expensive bibliography was already three years out of date when it went to press. Hence important new works like Watson's monograph on British forms of *Rubus* are not included. The publishers and authors might consider, therefore, issuing to purchasers a free mimeographed supplement bringing the list up to date. Generally this compilation will save time, but it is hoped that those who use it will not by-pass the originals, unless we may conclude that nowadays only summaries really need be published.

G. HASKELL

I.G.Y.

Year of Discovery—The Story of the International Geophysical Year. By Sydney Chapman. Pp. 112. (Ann Arbor: University of Michigan Press; London: The Mayflower Publishing Co., Ltd., 1959.) 40s.; 4.95 dollars.

THE International Geophysical Year, July 1, 1957–December 31, 1958, was the most successful example of co-operation between the nations there has ever been, and as well as being a landmark in the development of geophysics it may well be of significance in the present endeavours to increase international understanding. In his account of this enterprise, of the executive committee of which he was president, Prof. Sydney Chapman records how at first there was little enthusiasm for a successor to the two international polar years and then how the interest grew until International Geophysical Year committees from sixty-seven countries joined in and a wide variety of geophysical projects were undertaken, to be climaxed by the launching of the first Earth satellite on October 4, 1957.

But the book is not an account of the organization of the International Geophysical Year, important though this was. It is an excellent account of the scientific background of and the reasons for the projects undertaken.

Those familiar with Prof. Chapman's writings will not be surprised to know that this book is a model of scientific writing; the sentences are short and not encumbered by unnecessary words; a large number of useful facts about the Earth are to be found in the text; plates and diagrams illustrating the whole field of activity are included. It can therefore be recommended to students and to laymen who wish to acquaint themselves with what is known about the Earth, and there will be few, even among experts in geophysics, who will not learn something by reading it. S. K. RUNCORN

Progress in Semiconductors, Vol. 4

Edited by Dr. Alan F. Gibson, Prof. R. E. Burgess and Dr. F. A. Kröger. Pp. vii+291. (London: Heywood and Co., Ltd., 1960.) 63s. net.

THE series of review articles which make up the volumes of "Progress in Semiconductors" help very much to cut down the time which physicists, chemists, metallurgists and electronic engineers in this still rapidly expanding field have to spend reading the journals less familiar to them. Unfortunately the series can survey the whole field no more frequently than perhaps once every ten years.

The eight papers which make up the fourth volume are generally well written but expect quite a lot from the reader. The easiest to read are those on the oxidation of germanium surfaces (the Mott–Cabrera mechanism is ruled out for a clean surface), on internal field emission, which has been studied in *pn* junctions and in phosphors, and on the electrical effects of dislocations. In contrast a paper on negative mass demands some familiarity with quantum mechanics and another on avalanche multiplication demands confidence in expressions for the motion and scattering of electrons in high fields. A paper on noise in semiconductors shows that the components with spectral intensity $\propto$ (frequency)$^{-1}$ still need further study. The effect of dislocations on dielectric properties is studied in another paper in terms of ion movements, electron trapping and microwave observations. The last paper, of which A. F. Ioffe is co-author, directs attention to a large range of non-crystalline semiconductors including liquids, in which the carrier motion is very different from that in germanium and silicon. J. R. TILLMAN

Comprehensive Inorganic Chemistry

Edited by Prof. M. Cannon Sneed and Prof. Robert C. Brasted. Vol. 7: The Elements and Compounds of Group IVA. By Harold P. Klug and Prof. Robert C. Brasted. Pp. ix+302. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1958.) *56s. 6d.*

THIS book is one of a series in which an attempt has been made to combine an encyclopædic treatment of the chemistry of the elements with the inculcation of the basic principles of chemistry. When one considers the extent and complexity of inorganic chemistry to-day, it is clear that a good deal of information must necessarily be omitted if a whole group is to be covered in a volume of this size. For example, the historical background of each element is cut to a minimum (but Cornish tin (page 212) certainly reached Rome before the Roman conquest of Britain), and it is, perhaps, a little surprising that the uses of carbon-14 are scarcely mentioned and, in view of their uses in atomic energy, some reference might well have been made to cadmium and cerium glasses. However, the descriptive chemistry of the elements covered in this volume is presented lucidly and the result is a not unpleasing text-book which should be useful to the university student and to the research chemist, for whom the numerous tables of physical data will be of considerable value. The book is well produced, and the index, so far as tested, is adequate. K. W. BAGNALL

Histochemistry

Theoretical and Applied. By A. G. Everson Pearse. Second edition. Pp. x+998+10 plates. (London: J. and A. Churchill, Ltd., 1960.) 110s. net.

THIS is a vast guide-book to the fields of histochemistry. Twenty-nine chapters and twenty-seven appendixes provide a comprehensive and up-to-date account of the subject. In the spirit of "Baedecker" the author has practised all the available methods and rejected those found wanting. This enormously enhances the value of the book, but had the further step of a star system been taken to classify the many methods, the novice would be better served. There have been so many improvements and extensions since the first edition of seven years ago that this is virtually a new and better book.

The chemical and physical backgrounds to the techniques have been given so far as is practicable in a book of finite size. Readers with special knowledge of the various aspects of the subject will no doubt find omissions, misunderstandings and misplaced emphasis, but I have found no serious cases in my own special fields. With this volume as a guide, cytochemists can travel hopefully but might be more sure that they would arrive safely if an extended and quantitative account of the hazards and errors of interpretation due to diffusion during fixation and reaction had been provided. The illustrations, especially the colour plates, make this an attractive book to use, but have undoubtedly added to its high cost. Inexcusably the book is shoddily cased, and with a covering unlikely to withstand the hard use this book will undoubtedly have in all histochemical laboratories. L. G. E. BELL

THE MARANGONI EFFECTS

By L. E. SCRIVEN* and C. V. STERNLING

neering Department, Shell Development Co., Emeryville, California

under buoyancy les and drops in various
liquids.

ements

"On Certain ons Observable at the
Surfaces of W r Alcoholic Liquors",
published in 18 ish engineer and physi-
cist James Th ains the first correct
explanation of of a drop of alcohol on
the surface of l-known tears of strong
wine, and rel na. Thomson rightly
inferred that th f surface-tension-driven
flows were resp "numerous motions of
extremely won rs in fluids undergoing
evaporation" t d observed earlier with
the aid of a mic ilar microscopic studies
of convection vaporating drops were
made independ r[3].

Numerous f periments with surface
movements were erwards[4-7]; but Thomson's paper went unnoticed until van der Mensbrugghe's definitive memoir appeared in 1869 in a now obscure Belgian journal[8]. Van der Mensbrugghe reviewed all the earlier work, including the literature on the camphor dance dating back to 1686, and established that all the varied instances of surface movement were caused by local differences of interfacial tension. When Marangoni contested the priority of van der Mensbrugghe's finding[9], Thomson's paper again went unmentioned, and it is probably for this reason that the effect has come to bear Marangoni's name (cf. ref. 10).

The classic qualitative studies have been continued by more recent investigators: Marcelin devised surface engines[11], Loewenthal was fascinated by tears of strong wine[12], the Langmuirs discovered that surface movements enhance the rate of evaporation[13], and Jebsen-Marwedel found that surface-tension-driven flows critically affect mixing and wall erosion in glass-melting furnaces[14,15]. Photographs of tears of strong wine have recently appeared[16]. There have been discussions of the role of such flows in crystal growth[17,18], motion of protoplasm[19-21], transport of bacteria[21], surface fractionation[22], absorption and distillation[23], foam stability[24,25] and other phenomena[26,27]. Mention should be made of the thermodynamic theories of spreading of surface films[28].

The cellular convection patterns induced by surface tension that Varley[2] and others[3,19] saw were later the subject of Bénard's beautiful experiments[29,30]. Bénard's work inspired the Rayleigh–Jeffreys theory of convection currents induced by density variations in liquids heated from below. However, this theory is at variance with Bénard's experiments in several respects. From the new experiments of Block[31] and theoretical analysis of Pearson[32] it is now known that surface tension rather than density variations produced Bénard's cells. Meanwhile the Rayleigh–Jeffreys theory has been confirmed by other experiments to which it properly applies[33]. It is interesting that Sutherland was led to postulate density-induced convection currents in order to explain the surprisingly rapid attainment of equilibrium tension at certain newly formed gas-liquid interfaces[34]. Surface-tension-driven flows seem no less likely an explanation.

The periodic twitching of an air bubble in water, toward which a fine jet of alcohol is directed, seems to have been first described by Quincke[19], who showed that surface-tension-driven flow is responsible. Recently rediscovered in slightly different guise by Lewis and Pratt[35], the phenomenon has attracted great interest in the field of liquid-liquid extraction. A semi-quantitative theoretical analysis was made by Haydon and Davies[36,37]. Similar phenomena occur at all sorts of fluid interfaces across which material diffuses[38,39]. Notable is the extensive investigation by Wei[40]. This spontaneous agitation of the interface between two unequilibrated fluids, which has come to be known as 'interfacial turbulence', has not yet been taken into account in the classic theories of interphase mass transfer. In order to arrive at an adequate theory, it will be necessary to know precisely the conditions which give rise to interfacial turbulence as well as the details of the flows. We have considered the preliminary problem from the point of view of the theory of hydrodynamic stability, arriving at a partial understanding of the factors that determine 'Marangoni instability'—the onset of interfacial agitation driven by local variations of interfacial tension[41].

---

* Present addres ? Minnesota, Minneapolis 14,
Minnesota.

Our analysis shows how it is that some systems are stable with solute transfer in one direction across the interface yet unstable with transfer in the opposite direction (cf. ref. 42). It indicates the importance of solute diffusivity in the two phases, the viscosities of the fluids, the dependence of interfacial tension on composition, and other parameters. In at least some circumstances the phenomenon known as spontaneous emulsification seems to originate in interfacial-tension-driven flows[43].

Surface Elasticity and Viscosity

The resistance of a fluid interface to deformation was first noted by the blind Belgian physicist Joseph Plateau, famous for his researches on capillary action, especially the equilibrium configurations of liquid masses under the influence of surface tension (see his great treatise[44]). The different rates of damping of an oscillating compass needle suspended on one hand in the surface and on the other in the bulk of various liquids led Plateau to infer the existence of a 'superficial viscosity' peculiar to a liquid surface but analogous to the ordinary viscosity of fluids in bulk[44,45]. In so far as his needle subjected the surface to shear, Plateau's inference was substantially correct: since his time, measurements of shear viscosity and elasticity of surface films have become commonplace[25,46–51]. However, if surfaces of pure liquids have a peculiar resistance to shear, present experimental techniques are not sufficiently sensitive to detect it.

What Plateau did not appreciate is that virtually every liquid surface is contaminated with insoluble material to some degree, and that there exists an equilibrium between material dissolved in the bulk and adsorbed on the surface of solutions. Thus the advancing needle tended to concentrate contamination and adsorbed material ahead and to dilute them behind it. This produced a difference in surface tension on either side of the needle, the difference being of the proper sense to damp the motion.

Marangoni[52] first clearly recognized this effect in the experiments of Plateau, who remained unconvinced[53–55]. It remained for Gibbs to give it a completely satisfactory explanation[56]; hence the name, 'Plateau–Marangoni–Gibbs effect'[57]. There is a lucid and definitive paper on the subject by Lord Rayleigh[58], who made other valuable contributions to the understanding of surface movements and the resistance thereto[59–61]. The part played by the 'Plateau–Marangoni–Gibbs effect' in stabilizing free films and foams has long been recognized in a general way, often under the name 'Gibbs elasticity' (for example, ref. 25). But the "profound analysis of the act of thinning of a film" called for by Derjaguin and Titijevskaya[62] has not yet appeared. The mathematics of such an analysis is formidable, owing to the complicated velocity and concentration fields involved.

As Birkhoff observed in connexion with the 'rising-bubble paradox', the mechanics of real fluid interfaces is far less simple than the classical hydrodynamic treatments would suggest[63]. The paradox is that the motion under buoyancy of small bubbles and drops through a liquid is usually much closer to the behaviour of rigid spheres than to that expected for fluid spheres capable of internal circulation. But in systems cleansed of interfacially active material, the paradoxial behaviour does not occur, except with the smallest of bubbles and drops[63,64]. The seeming exception may be due to the extreme difficulty of eliminating the last traces of interfacial contamination[6,46,56,58,65]. If circulation of the bubble or drop is retarded or arrested, there must exist a force not contained in classical hydrodynamics which opposes the viscous traction exerted on its surface by the surrounding liquid; and because the viscous traction tends to expand the surface phase over the leading hemisphere and contract it behind, the 'Plateau–Marangoni–Gibbs effect' is sufficient to account for the existence of this force. The first to recognize this was Boussinesq[67], who showed that any viscous-like resistance to dilational deformation of the surface, whatever its origin, causes fluid spheres to move more slowly than expected from classical treatments, in which the possibility had been overlooked. Modern mathematical analyses have shown how the kinetics of adsorption of soluble surface-active materials can account for a 'dilational surface viscosity'[68,69]. The Marangoni effect mentioned above may also enter; for with mass transfer between the dispersed and continuous fluids, as occurs in liquid-liquid extraction and related operations, there may be a sufficiently high concentration—hence also interfacial tension—gradient in the proper direction along the interface to arrest or even reverse the internal circulation. The entire situation of drop circulation and the effects of surface-active materials was recently discussed by Linton and Sutherland[70].

The role of shear viscosity and elasticity of surface phases and of the 'Plateau–Marangoni–Gibbs effect' in other free boundary flows has been considered by at least a few hydrodynamicists after Aitken's discussion of the calming action of oil on capillary waves on the surface of water[71]. Specific reference should be made to the writings of Lamb[72], Levich (as cited by Fedosov[69]), and especially Oldroyd[73], whose theoretical work on the effect of surface properties in the rheological behaviour of emulsions is partly confirmed by the recent experiments of Nawab and Mason on the viscosity of dilute emulsions containing surfactants[74].

The resistance of fluid interfaces to deformation is manifest, though not yet completely understood, in the stagnation of portions of interfaces in certain liquid-liquid extraction[25,41,75], gas absorption[76], and vacuum distillation experiments[45,67].

Quantitative understanding of the dynamic behaviour of fluid interfaces requires that their mechanics be described mathematically. The earliest attempts at this seem to have been made by Tait, who considered the effect of flexural-rigidity of a surface on ripples in a viscous fluid[77], and by Basset, who examined certain consequences of interfacial behaviour that allows slip between two phases in contact[78]. The most useful description for approximating the behaviour of real interfaces is that begun

PART-TIME COURSES IN FURTHER EDUCATION

By J. HEYWOOD
Norwood Technical College, London, S.E.27

THE correctness of the comment in *Nature* of February 6 on the Crowther Report is shown by the attitude of both the Government and the Opposition in their discussions. Too little attention has been paid by the Committee to the problems of day release teaching and student difficulties in technical colleges, nor has this been related to the secondary modern school leaver. *Nature* rightly suggests that little consideration has been given to the lower streams of the secondary modern school.

A recent survey (which it is hoped will be published in detail later this year) supports the view that there are a number of students who will not benefit by any form of further education. Table 1 gives the percentage pass mark of a first-year intake studying eventually for the Radio Trades Board's examinations. The examination was on calculations taught in a 24-hr. course of basic arithmetic and algebra. When studied with the corresponding results of first-year intakes over the preceding three years a safe assumption is that those students scoring below 40 per cent in similar tests do not benefit from this type of education. Schedule *B* of Table 1 gives the practical marks for the same period. These are also typical of all the intakes, and there is not necessarily an increasing practical ability with the decline in marks gained in the theoretical examinations. Inquiries made at other technical colleges confirm this view. However, these inquiries also suggest a further subdivision in the classification of apprentices. This is referred to in items 3*a* and 3*b* of Table 2. The results of this particular survey indicate that it is impossible to classify the rejects from 3*a* as students who would have benefited by following a course of studies more appropriate to 3*b*. There are a large number of persons in semi-technical occupations who do not benefit by further education. The fact that many students are quite obviously unsuited for the careers they have chosen is both the fault of the employer and the careers specialist in the school and may influence the mobility of labour more than would be anticipated.

However, studies of the teaching methods applied to groups 3*a* and 3*b* arising from an examination of the problems of wastage in group 3*a* suggests that entirely different approaches are required for the two groups and that those in group 3*a* would benefit from a year's full-time study of their subject. Group 3*b*, into which fall trades such as carpentry, plumbing, automobile engineering, apparently gain more from an apprenticeship with day release over a period of five years than do those in group 3*a* (for example, those students who pursue radio and television servicing courses), where the wastage over the first three years is large. Table 3 shows the decline in student attendance over the three years which is necessary for the Radio Servicing Certificate. The main causes of wastage are as follows: (1) insufficient ability to cope with studies; (2) refusal of the employer to allow more than one or two years part-time education; (3) change of occupation: (*a*) within the trade but to an employer who does not allow day release, (*b*) to employment in another trade; (4) completion of articles during the period of study; (5) decline of interest on the part of the student.

The wastage due to apparent low intelligence quotient was considerably reduced by changing the teaching methods from one year to the next. Following up in the third year with the improved methods of teaching did not, however, maintain the pass percentage, thereby supporting the view that there is a minimum level of intelligence quotient required for satisfactory attendance on this type of course. Further support for this view is gained from Table 1, where only one of the three students referred from the previous year to repeat the course passed the calculations examination.

Table 1. MARKS OBTAINED BY FIRST-YEAR STUDENTS IN INTERNAL CALCULATIONS AND PRACTICAL EXAMINATIONS

Student	*A*	*B*	*C*	*D*	*E*	*F*	*G*	*H*	*I*	*J*	*K*	*L*	*M*	*N*	*O*
Schedule *A*	84	77	73	70*	68	55	55	48	48	48	45	39*	37	27	*a*
Schedule *B*	60	70	70	60	50	50	40	40	50	60	50	50	40	20	
Schedule *C*	45	50	50	60	45	45	50	75	40	40	35	50	30	25	

* Students repeating the same year of studies; *a*, student absent but unlikely to pass examination on basis of previous marks.
Percentage pass = 42·8 per cent. Percentage pass on a simple average = 57 per cent.
Schedule *A*, calculations examination; schedule *B*, practical examination; schedule *C*, previous terms practical marks.

Table 2. CLASSIFICATION OF APPRENTICES COMPARED WITH THE LEVELS OF QUALIFICATION SUGGESTED IN THE CROWTHER REPORT

Schedule *A* Classification of apprenticeship	Schedule *B* Type of further education	Schedule *C* Levels of qualification for industry
(1) Graduate	Within industry	Technologist
(2) Student	Sandwich or part-time day	Technologist
		Technician
(3) Trade:		
(*a*) Technician, for example, radio and electronic servicing	Part-time day or evening over 4 or 5 years	Craftsman
(*b*) Craftsman or artisan, for example, building plumbing		Craftsman
(4) Operative	Short period of industrial training	Operative

Table 3. ILLUSTRATION OF THE DECLINE IN ATTENDANCE OF PART-TIME DAY RELEASE STUDENTS OVER THE THREE YEAR PERIOD OF THE RADIO SERVICING COURSE

Course	First-year enrolment (per cent)	Per cent passing end of first-year test	Second-year enrolment (per cent)	Per cent passing intermediate certificate	Third-year enrolment (per cent)
A	100	36	36	36	18·1
B	100	42·[illegible]	31·5	21 05	21·05
C	100	20·4	20·0	continuing	

N.B. The percentages refer to the original first-year enrolment and thus to the same groups of students. They do not refer in later years to students entering the course with exemptions from previous parts of the course. Average number in each intake = 14.

Table 5. ANALYSIS OF PART-TIME EVENING INTAKE SEPTEMBER 1959
Total intake, 63. 61 inquiries made. Wastage assessed for April 1, 1960

Student category	Percentage of total intake	Average age
(1) Students under 21, in trade	21 3	17 4
(2) Students under 21, in industry	21 3	17·8
(3) Students under 21, not in trade or industry	1·6	17 0
(4) Students over 21, in trade	19 6	—
(5) Students over 21, in industry	16 2	—
(6) Students over 21, not in trade or industry	20 0	—
(7) Total per cent of students with less than 50 per cent attendance	31 0	—
(8) Students under 21 with less than 50 per cent attendance	18 01	—

Finally, support for this idea is obtained from an analysis of wastage on evening courses. Table 5 gives the data for a first-year course enrolled in September 1959. The wastage at the time of writing is one-third of the total intake, but of the twenty-six students under twenty-one who are eligible for part-time day release free only seven have stopped attending, but studies of past wastage suggest that this figure will have doubled by the end of the second year. It seems clear that some form of test should be adopted with the view of establishing the worthwhileness of sending a boy on a part-time course in addition to Mr. Thompson's (*The Times*, April 3, Parliamentary Secretary to the Minister of Education) consideration that day-release should possibly become a legal right.

I am indebted to Mr. G. L. Danielson, head of the Department of Telecommunications Engineering, Norwood Technical College, for permission to publish some of the results of this survey.

taxonomy of bacteria

especially has been carried on as isolated fragments of other disciplines such as medicine or dairying, with the result that the same micro-organism has been known by a different name in each field, and not infrequently their identity has never been realized. Many taxonomic schemes have been devised but have been only cherished by their authors, while others such as Bergey's scheme have been tolerated with much vexation and disappointment for want of something better. Little wonder then that a despairing spirit has pervaded the subject and that Topley and Wilson should comment that "the bacteriologist himself has not in general troubled overmuch as to the validity of a system which has developed rather as a result of luck than of cunning"[1].

In the past few years, however, there has been a renewed interest in taxonomy associated with new ideas and concepts which have stemmed from two main sources, biosystematics and quantitative taxonomy. Some drastic changes in the underlying philosophy of taxonomy are now being proposed. Some of these centre on the nature and definition of taxonomic groups. It is being realized that bacterial taxonomic groups need not be treated as though they are necessarily phylogenetic. Other developments are based on the assertion that every feature has equal weight in the creation of valid taxonomic groupings. These developments are coming to be called the 'Adansonian method' after the botanist Michel Adanson (1727–1806), who first proposed this concept. By liberating biologists from the impracticable task of allocating different weights to different features it has been possible to develop the use of multivariate analysis employing electronic computors to give some measure of the elusive property which all biologists recognize under such phrases as 'overall similarity', 'affinity' or 'natural resemblance'.

Microbiologists may perhaps compliment themselves on the eagerness with which they are exploring these developments and indeed devising new taxonomic techniques of their own. The outlook in microbial classification has greatly changed and it was this which led to the invitation of a wide range of workers in microbiology, botany, zoology, statistics, biochemistry and electronic computing to attend an informal meeting to discuss these new points of view. The meeting was held on January 12, 1960, at the National Collection of Type Cultures at Colindale, London.

Dr. P. H. A. Sneath (National Institute for Medical Research, London) introduced the subject of quantitative taxonomy and summarized the present position on Adansonian methods. He emphasized the distinction between identification methods, that is those intended to distinguish existing taxonomic groups, and Adansonian multivariate techniques designed to create the taxonomic groups.

Dr. G. D. Floodgate (Torry Research Station, Aberdeen) discussed the problems of anyone trying to do bacterial taxonomy. He mentioned that the accurate identification of bacteria was no mere academic exercise, but a necessity for anyone involved in such fields as the ecology of the soil or the sea; and that identification is impossible when there are neither satisfactory bacterial taxa nor a coherent theory of taxonomy. Despite advances in theoretical taxonomy, there was still the problem of selection of features for taxonomic use, and of course the perennial problem of standardizing the techniques. He also thought that not enough had been done on the theory of hierarchies, and on whether to split taxa or bring them together.

Mr. J. S. L. Gilmour (Botanic Garden, Cambridge) found the Adansonian approach to be very interesting and of wide application—it has even been applied by anthropologists to myths and legends. He agreed that Adansonian methods yield valuable taxonomies for general purposes, but he cautioned against an 'absolutist' approach on the grounds that one must always make some selection of attributes of living creatures, and this selection is always guided by what one is interested in. The mathematical analyses are thus only summaries of mutually agreed classifications based on attributes selected for a particular purpose, and should not be thought of as expressing, in any sense, 'ultimate realities'.

Dr. S. T. Cowan (National Collection of Type Cultures, Colindale) discussed the problem of rank, and pointed out that this is commonly a matter of opinion even when agreement has been reached on taxonomic relations. In addition, the isolation between the different practical sides of microbiology—medical, industrial, agricultural and so on—has badly hampered a unified taxonomy. Dr. G. C. Ainsworth (Commonwealth Mycological Institute, Kew) suggested that agreement might eventually be reached on mathematical values for differentiating between species. Dr A. J. Cain (Department of Zoology, Oxford) made a plea for a simple nomenclature with few rules, and mentioned the advantages of uninomial names. Dr. C. H. Andrewes (National Institute for Medical Research, London) pointed out that some virologists were now considering the possibility of doing this for the viruses.

Dr. R. R. Sokal (University of Kansas and University College, London) then defended the practice of equal weighting of features for the creation of taxonomic groupings, pointing out that it is well-nigh impossible to justify differential importance of features on any rational grounds, whether genetic, adaptive or phyletic. Attempts to do so were vitiated by unsuspected logical fallacies which have only recently been challenged. He also pointed out that Adansonian methods led to a very stable taxonomy.

Dr. M. Ingram (Low Temperature Research Station, Cambridge) was doubtful whether the equal weighting of features would lead to a better classification than that where the features are weighted.

Dr. N. J. Berridge (National Institute for Research in Dairying, Reading) and Dr. C. S. Cummins (London Hospital Medical College) described recent techniques using paper chromatography which enabled the composition of bacterial extracts and of cell walls to be applied to taxonomy. The use of infra-red spectroscopy was also mentioned. Dr. Cain pointed out that such methods give a flood of new characters which must be co-ordinated with previous taxonomic knowledge. He instanced the comparative serology of birds. Dr. Ainsworth mentioned that recent nutritional and physiological studies had confirmed the taxonomic results obtained by the traditional morphological approach to certain groups of fungi.

In addition to the above there was some very lively discussion in which almost everyone present took part, and which ranged over a very wide field including methods of mathematical analysis, sampling methods, nomenclature, genetics and serology.

As a result of this discussion it was agreed that it would be very useful to form a Group of those interested in microbial systematics within the Society of General Microbiology. Accordingly, with the approval of the Committee of the Society, the Group was constituted at a meeting held in London on April 12, 1960. Drs. Cowan, Sneath and Shewan were asked to act as a small committee to organize the activities of the Group, and Dr. Sneath agreed to be the secretary. The purpose of the group is to promote the advancement of microbial systematics by providing a common meeting ground for those interested in the field. It is envisaged that the Group will hold discussions, arrange for the interchange of information and ideas between microbial taxonomists and taxonomists in other fields of biology and, in general, to assist its members to make the best contribution to this field that they may. Membership of the group is open to all members of the Society of General Microbiology. Visitors will, of course, always be welcome at any meetings the Group may hold. Anyone wishing to be kept in touch with the Group's activities, or desiring further information, is invited to contact Dr. P. H. A. Sneath, National Institute for Medical Research, The Ridgeway, Mill Hill, London, N.W.7.

uptake of lead. The dilution is such that the radium may not be an assemblage of cations. As in the case of strontium-90, the calcium ratio is of interest. Two experiments by the N.Z. Grasslands Institute may be quoted. In the first, 'Brown Top' was grown on the same soil, *p*H unlimed 5·4, limed 5·6. The α-activity per gram of ash was 1·7 μμc./gm. unlimed, 1·22 limed, a significant decrease. In another experiment on a severely leached acid podzol at Kaikohe, activity 5·4 μμc./gm. 15 cwt. superphosphate per acre was added generally nearly two years ago, accompanied by (1) 20 cwt. lime (66 per cent $CaCO_3$); (2) 60 cwt. lime; (3) a lime pile. In case (1), the *p*H at 0–3 in. became 5·2 and cation exchange capacity 7·2, and ryegrass grown on it gave 2·8 μμc./gm. ash and White clover 3·1. In case (2), the *p*H became 6·1 and cation exchange capacity 9·5, while ryegrass gave 2·8 and White clover 3·2. In case (3), the *p*H was 7·4, ryegrass 3·3 and clover 3·9 μμc./gm., with 9 and 18 per cent contribution by thorium, respectively. The average lime (CaO) content of the ryegrass ash was 6·75 per cent and of the clover 15·25 per cent, so that expressed as per gram calcium the ryegrass gave twice the pick-up of clover, although on dry-matter basis clover gave roughly 10 per cent more than ryegrass (ash/dry-matter = 0·1). This latter may be contributed to by a correspondingly increased portion from thorium products, 18 per cent as against 9 per cent, although long statistical counting would be necessary to test this point sufficiently. One needs, perhaps, experiments with basic slag instead of superphosphate to avoid definitely the radium carried with the latter. A sample of the lime used gave an α-activity of 3·5 μμc./gm. with some 60 per cent contribution from thorium products.

In another series of field tests in the United Kingdom on five different soil types, the ashes of ryegrass and lucerne gave, in each case, approximately the same α-ray activity. I do not have calcium/ash determinations.

Measurements were also made of wheats grown in the United Kingdom, New Zealand and Victoria (Australia). Total variations of nearly 20 : 1 were observed in the α-activity per gram ash, the activity being mainly controlled by *p*H and calcium exchange availability status, with genetic variety as a significant, but quantitatively less important factor. It is worthy of note in passing that the average soils growing wheat and pasture in the United Kingdom appear to have a markedly higher *p*H and corresponding lime status than the soils of New Zealand. This is possibly the influence of extensive greywacke wheat-growing soils in the latter with *p*H about 5·5, but it results in a very different degree of proportional uptake of radium and presumably of strontium-90 from soil. This factor may also have a bearing on the high results (*Nature*, September 12, 1959) of strontium-90 pick-up reported in the case of the acid soils at Tatyoon, Victoria. Similarly, such considerations in relation to foodstuffs and water may need to be taken into account in interpretating the interesting observations on inhabitants living on the acid granite soils

Table 1

	Material	Ash (per cent of wet weight)	Activity of ash (μμc./gm.)
Niue	Taro (4)	0·8	50–300 CaO 6·1 per cent

United Kingdom	Wheat	1·8	c. 0·9
New Zealand	Wheat	1·42	c. 2·3

In the above the first four figures refer to roots. The leaves of taro showed little activity. Kumeras from some parts of Niue showed little activity.

of New York State[3]. It is intended to deal with the various results on wheat and cereals in conjunction with E. D. Greer, of the British Flour Millers Research Association, with whom I collaborated in this section of the work.

In the previous paper, reference was made to the high activity of the soils of Niue Island (long. 19° S., lat. 170° W.), and although the advent of a destructive hurricane has delayed an extended personal visit for observations, yet the readily given help of the administrative officials concerned and particularly of the agricultural officer, F. W. Van Westendorp, has enabled many useful samples to be collected and interesting data to be assembled. Moreover, by courtesy of the Royal Navy (New Zealand), Lieut. A. Mitchell, during a brief visit of H.M.N.Z.S. *Royalist*, made a survey of external γ-radiation and recorded values up to 0·13 mr./hr. over a large area of soil, or some twelve times normal elsewhere. This measurement was taken in the open air. The soil content of radium would correspond to several times this value, as the radon, etc., is given off very readily under natural conditions at Niue.

A variety of ashes of plants grown on the agricultural area of Niue gave the equilibrium activities (1 month) shown in Table 1. Figures in brackets refer to number of samples tested.

In all Niue cases the plant activity is due mainly to radium, though further work is called for, as after nine months the above values were increased 30 per cent in the case of taro, kumera and cassava and more in the case of yam. It may be due to radium-D or other nuclide which produces an α-ray product. Unfortunately, measurements of soil *p*H, etc., were not readily possible, though a general survey of the soils is, I understand, in course of publication by the N.Z. Soil Bureau, and values are of the order 7. Small pieces of coral are disseminated through many of the soils, and it is probable that *p*H was not uniform.

The main foodstuff consumed (80 per cent) by the Niueans is taro, which is seen to be very radioactive indeed, particularly if related to calcium; and since the soil is porous and the drinking water supply is roof-collected rain water, the taro was formerly, except for limited supplies of flying fish, the main source of calcium for bone-growth and maintenance. During the past thirty years, however, increasing supplies of skim milk powder have been consumed, containing calcium of negligible activity. Reconstituted milk is now given to all school children.

Activity of Soil and Origin

As to the parent soil, although only one chemical analysis for uranium has been carried out, giving 59 p.p.m., estimations were made by observing the growth of activity after dissolving with acid and igniting so as to compare the growth of radon and products with similarly treated uranium minerals. Measurements by γ-rays on one soil sample so treated gave 30-fold increase when the radium had attained equilibrium, indicating little uranium-X. In the case of α-rays, typical rough figures for the ratio of activity after a month to initial value were: standard uranium mineral, 1·85; island phosphates, 1·95; Niue soil, 3–4; Niue taro ash, 4; bones of Niue 'bush' hen, 5.

In interpreting these figures, there is uncertainty in the amount of polonium present or driven off by heat—since most of the soils readily give off emanation. Moreover, with the thick-layer counting method used, the greater ranges of radon, radium, radium-A and -C, in comparison with uranium, ionium and radium needs to be taken into account. For example, if the activity is wholly due to ionium + radium in equilibrium with one-third equilibrium polonium, the ratio should be approximately 3. Uranium analyses and radon determinations are needed or a pulse analyser which will resolve uranium-II, ionium and radium. It is obvious, however, from the above that the radium in the soil is several times greater than that supported by the uranium present. It may possibly be that the radium is in excess even compared with its ionium parent. It was at first suspected that the uranium-235/uranium-238 ratio might be higher than the usual 1 : 139. This was negatived later by tests in the United Kingdom with a mass spectrograph on one sample; but in the meantime tests for the daughter products of uranium-235, that is, actinium, had proved interesting. The output from the scintillation photomultiplier was divided and the two channels counted in the manner used by Turner, Radley and Mayneord (*loc. cit.*), but with an interval of about 0·005 sec. in the subsidiary channel instead of 0·32 sec. as used for the determination of doubles due to thoron and thorium-A. The idea was to obtain a measure of actinium-A (half-life 0·002 sec.) and thus of the actinium family.

The results are shown in Fig. 1. No attempt is made at this stage to denote statistical limits of accuracy. Enough doubles were measured in each case to justify the general placing of the points on the graph. Before using the method quantitatively, some study of material distribution, particle size, and spaces in the capsule are called for. At the rates used, the number of spurious apparent doubles should be approximately related linearly to count-rate[4], as indeed is shown by the figures for the various plutonium and other sources not carrying actinium. Incidentally, the plutonium was obtained from ashed bones of small experimental animals—into which plutonium had been injected. As expected, uranium mineral shows residual doubles due to its content of actinium; Travancore sand a lesser number. The soil samples from Niue, etc., do not appear at first sight very abnormal, but it must be appreciated that the content of uranium is far from sufficient to support the other nuclides which contribute to the rate observed, so that the Niue soils must carry excess actinium. However, probably an equally interesting result is that obtained with fossil phosphates such as Nauru, which although as noted above are reasonably in equilibrium as regards uranium-238–radium, etc., indicate an excess of actinium. In Fig. 1, the positions of the points are approximate, but taken together the evidence seems definite and

of the thorium family, variable but of the order of 50 per cent. The results were checked on material collected later, during a Pacific voyage by H.M.N.Z.S. *Royalist*, and also on samples at different depths collected by the N.Z. Oceanographic Institute. Moreover, tests were made of the activities of some of A. T. Wilson's foam samples and of mussels and certain sea organisms, and in some cases enhanced activities were found. The results are not sufficient, nor was the material well enough classified; but they do show that the above suggestions merit the making of tests of sea-surface organic matter at Niue, etc., and the gathering of more experimental information on the geochronological aspects of ionium and actinium. Tests of limestone from shell moulds and from pits showed much radium leached from above. This distribution is being investigated.

Activity of Bones and Radiation Hazard

It is natural to extend the observations to the activities of human bones and body organs, but so far opportunities have not presented themselves. Thanks to the Niue Island Dental Service, however, a good supply of teeth has been made available for comparison with teeth from other localities. The average activity of Niue teeth per gram ash was some ten times that of teeth of Londoners, as was confirmed also by measurements at the Institute of Cancer Research by Miss M. Duggan. The average of twenty Niuean teeth was 1·8 μμc./gm. Samples from Hastings (New Zealand), where the soil and water are well supplied with lime, gave a value 0·32, Raratonga 0·2, Lower Hutt (where low-activity calcined lime is added to the artesian water to bring the pH to 85) 0·4, Auckland, Wellington and Sydney, N.S.W., c. 0·7. In all cases the activity is mainly due to radium—in Niue, almost wholly so. The relative contribution by food supplies and water supplies to teeth and skeletal radium is not yet known. Independently of lime fortification, the flour in the United Kingdom contains considerably less radium per gm. ash than in New Zealand or Australia. However, the above results are to be taken as approximate—they relate to a few samples only; there is possibly an age relationship. Thus the teeth of ten adults of age seventy, kindly supplied by the superintendent of the United Dental Hospital, Sydney, gave a preliminary average of 0·4 μμc./gm., whereas unerupted teeth of children aged twelve gave a value of 1·0 and erupted children's teeth of about the same age 0 5. Breakfast foods from Australia were examined, and no case of added radioactive material was found, as was the case in two brands from the United Kingdom. The relative low activity of teeth of elderly people may have a similar explanation to that given in my earlier article and relating to sheep of forty years ago, or some deposited nuclide which decays with time.

Teeth extracted from skeletons found in limestone caves of Niue, but of unknown age, gave the same value as present inhabitants, indicating presumably that the radioactivity has been a feature of Niue for at least a few hundred years. It is reported that fine grains of charcoal have been found in underground caves into which surface water readily drains. If so, and if these are connected with the effects of an ash shower, it should be possible to obtain a date by carbon-14 methods.

Probably the most interesting results obtained were those of the bones of hens. The bones of nondescript breed, so-called 'bush' hens, fed on the country, plus a certain amount of local dried coconut, gave 60 $\mu\mu$c./gm. bone ash. This, in humans, would be greater than accepted tolerance. The bones of recently imported Rhode Island hens at the prison farm and fed on wheaten mash imported from New Zealand, gave a value of 24, while a single sample of the contents of two eggs from the latter gave a value of 4·4. If this latter result is confirmed, it will correspond with the discrimination or reduction in activity of the foetal offspring in the case of the cow and ewe, as recorded in my previous article. It appears that the same discrimination may not occur in the case of humans, though it is said to occur in the strontium-90/calcium ratio, but the activity of normal human bones is in any event only about a tenth of those of cows, sheep and rabbits.

The Niueans appear to be healthy and vigorous, though somewhat sparer than the other Polynesian groups, to which they are racially related. Probably they have to work harder. With such a small population, namely 4,500, great care is necessary in treatment of statistics of cancerous conditions or of congenital malformations or impairments which might be associated with the large background γ-radiation and food α-activity. Similarly, regarding the occurrence of plant mutations—these are indeed observed in bananas and other plants, but there is as yet no comparative data from other Pacific islands showing less natural activity.

One might expect the possibility of an abnormal sex ratio, and this question is being looked into by the School of Demography, Canberra, which has made a close study of Pacific Island populations. As to fertility, the following figures deduced from a report kindly made available by Drs. McCarthy and Marples, of Otago, may be significant. These authors visited a village in Niue in 1955 for the purpose of investigating certain blood conditions and incidentally noticed the predominance of childless marriages and were led to a close investigation of a group of 100 cases. At that time the high radioactivity of Niue was not known. The figures are: childless marriages, 19 per cent; stillbirths, 6·1 per cent; infant deaths, 9·8 per cent; deaths 1–3 yr., 6·35 per cent. Figures for marriages about 1925 were higher than the more recent; in fact, the infant mortality is now much lower, but an improvement had occurred before the advent of antibiotics for treatment of venereal disease, etc. It is possible that the distribution of skim milk from the hospital, which started nearly thirty years ago, has in some cases had the effect by replacing the calcium from taro with its high radium/calcium ratio by calcium of milk with negligible radium content. Similar evidence might be deduced from the history of a certain hamlet of Fatiau, of 85 persons, established some eighty years ago, the inhabitants of which, knowing nothing of radioactivity, yet were constrained to move as a whole ten years ago to a more wind-exposed site, Vaiea, 2 miles away, because of unknown but feared causes of infertility and infant mortality. However, I am well aware of some of the pitfalls of such statistics; epidemics of influenza or measles can in these islands make great differences in the figures in particular quinquennia; and similarly fashions in diagnosis, etc., change. But if the causes of low fertility are contributed to by high local radioactivity, may it not be that in the Darwinian sense selective breeding of resistant types has taken place? It would appear that Niue has been populated for fully a thousand years. There is ample evidence that different strains of small animals differ markedly in resistance to radiation.

It is hoped to plan carefully and carry out an investigation of these problems during the coming year, and suggestions and help are invited to this end. If the results of Gentry and Bulin (*loc. cit.*) are due to other than selective population migration, then these questions are very important indeed.

In conclusion, I would like to thank all those who have kindly assisted so freely, in particular, W. H. Ward, director of the laboratories at the Dominion Physical Laboratory, for providing laboratory space, etc.; A. H. Allen and Mr. Penton, of the Electronics Division, for improvements to the apparatus; Dr. J. K. Dixon, of the Soil Bureau, for useful soil discussions; and the staff of the Coal Survey Laboratory and Dominion Laboratory Division for ashing facilities and analyses; the secretary of the N.Z. Island Territories Department and the Niuean Administrator for advice on Niue matters; the agricultural officer, F. W. van Westendorp, for provision of samples; and lastly, the manager and officers of the Blue Star Line for facilities to make measurements on board ship during three voyages. The ships proved to have low contamination and background activity, and enabled reliable measurements to be made more easily than on land.

OBITUARIES

Sir Robert McCarrison, C.I.E.

MAJOR-GENERAL SIR ROBERT McCARRISON, who died in Oxford on May 18 at the age of eighty-two, was a pioneer of nutritional research whose scientific reputation was even greater abroad than in Great Britain. Particularly is he remembered in India, where he spent much of his life.

After graduating M.B. at Belfast in 1900, McCarrison immediately entered the Indian Medical Service. At his first station he encountered and investigated what he correctly believed to be a fever transmitted by the sand-fly (*Phlebotomus*), and then he began a classical investigation of goitre and cretinism in the foothills of the Himalayas. He noticed the connexion between polluted water and endemic goitre, and he produced this condition in himself and volunteers by drinking the suspended matter of grossly polluted water.

He then tur eriberi in particular, and
nutritional d meral. Little work on
these lines had ndia, though McCarrison
was particular by the work of McCay
(1912) on the f dietary protein. His
approach was successful; he realized
that single die s were unlikely to occur
in man, and t might well be produced
by combined lo he fed lower animals
such as rats or poor diets being used by
various tribes, in the animals diseases
similar to thos occurring in such tribes.
This type of a very different from that
of Hopkins, M is and others, who were
feeding lower purified diets. Both
approaches we d it is surprising that
short-sighted led criticism at McCar-
rison's method med up in these words:
"My own met ther hand, has been to
observe the m ymptomatic and patho-
logical effects c on the animal body as a
whole, and the in what forms of human
illness might r attributed to it". This
approach led t pers on the pathogenesis
of deficiency d

He met criti from scientific colleagues
but also from Department. His work
was frequently much he paid for him-
self. In 192 hgow visited India as
chairman of t mission on Agriculture,
and insisted or McCarrison's work. The
Commission re mportance and promise
of what he wa moor; and in 1929 his
unit was made trition Research Labor-
atories, now m abad.

In 1935, Mc d and settled in Oxford.
He and Lady who survives him, kept
open house, an stant visitors, especially
in the form of ldren and distinguished
scientists from ring the Second World
War, McCarris rman of various com-
mittees, and du he was the first director
of postgraduat ation in the University.
His academic e many, and he was
knighted in 19

His more im were edited by me and
presented to h *rift* on his seventy-fifth
birthday. Not m more than a telegram
from the Mini h of India, Rajkumari
Amrit Kaur, ex ratitude of that country
for his great ser ence of human nutrition
and the advan public health.

H. M. SINCLAIR

ROBERT K COFIELD, reader in soil
science in the Oxford, died on June 8,
at the age of fi

He entered e, Cambridge, in 1919,
obtained a firs of the Natural Sciences
Tripos, and th country dancing. In a
testimonial, J. '. . . was impressed by
the promise he ad ideas and the energy
and skill to t experiment". Already
interested in sics, Schofield sought
research experi lloid Science Laboratory,
and his first tw h E. K. Rideal) were on
the kinetic theory of surface films. After two years at Durham (1926–28) as lecturer in physics, he joined B. A. Keen at Rothamsted Experimental Station with an introductory description from I. O. Masson that fitted Schofield throughout his life: "As a physicist he is all round. He is a very nice fellow indeed, full of go and good spirits, and we all like him."

Schofield spent twenty-seven years at Rothamsted, succeeding Keen as head of the Physics Department in 1949, and then took charge of the much bigger Chemistry Department on the death of E. M. Crowther in 1954. Two years later he moved to the Department of Agriculture, Oxford, so returning to the academic atmosphere for which he always had a great affection.

Though his early Rothamsted work was mainly on the rheology of clays and similar materials, done in collaboration with G. W. Scott Blair, by 1935 he had also published papers on proteins, on the diffuse double layer—and on soil water. One of these was "Schofield (1935)", perhaps the most quoted reference in the literature of soil science. Others have expanded his thermodynamical treatment—a few think they have improved it—but "The *pF* of the water in soil" still remains the basis of any worth-while discussion of soil–water equilibrium. Leaving problems of bulk movement to those interested in drainage and evaporation, Schofield concentrated on the behaviour of water as an electrolyte in contact with the charged faces and edges of clay particles. His ideas on the ionic forces in water films were used in physical studies of soil structure, soil permeability and soil rheology; and in chemical problems of soil acidity, cation exchange, and the availability of nutrients.

There will be widespread regret that he did not write a synoptic survey of this work and of his ideas for its future development, but even without it Schofield leaves behind him an enviable world reputation in soil science and related technologies. Part of this was attained through his publications (more than eighty as sole or joint author), and part through an extremely wide range of personal contacts. There seemed to be no limit to his fund of ideas, and they were passed on liberally to anyone willing to listen. As a consequence, he was much in demand, nationally and internationally, for committee work and for discussion meetings. Selecting only a few events and activities in his career, Schofield was chairman of the Colour Group of the Physical Society; for six months, 1951–52, he was visiting professor at Cornell University; at the time of his death he was president of the British Society of Soil Science, and chairman of Commission I of the International Society; and, specially pleasing to him, he had an honorary doctorate conferred on him in Lisbon in 1956.

Throughout a very busy life, his main interest outside science was in country dancing, and he was an enthusiastic performer and administrator in the English Folk Dance and Song Society; at the time of his death he was 'Master Squire of the Oxford Morris Men'.

In his combination of qualities as man and as scholar, Schofield was unique and irreplaceable. He leaves behind a host of grateful friends, at Rothamsted, in Oxford, and elsewhere, all proud of their association with him.

H. L. PENMAN

NEWS and VIEWS

Mathematical Physics at Birmingham :
Prof. S. Mandelstam

Dr. Stanley Mandelstam, who has been appointed to a new chair of mathematical physics in the Department of Mathematical Physics of the University of Birmingham, comes from South Africa, where he graduated in engineering and in science (physics and mathematics) in the University of the Witwatersrand. As a student he was a co-author, with W. Yourgrau, of a book on the "Variational Principles in Dynamics and Quantum Theory". It was published by Pitman in 1955. He took Part 2 of the Natural Sciences Tripos and Part 3 of the Mathematics Tripos in Cambridge, and his Ph.D. in mathematical physics in Birmingham in 1956, and he has since carried out research in Birmingham, Columbia and Berkeley. His first original papers were concerned with quantum field theory and with the phenomenological description of pion production in nucleon–nucleon collisions. He is best known, however, for a new method in quantum field theory, now known as the Mandelstam representation, in which the general analytical approach of dispersion relations is generalized to the treatment of a scattering or reaction amplitude as a function both of the energy and the momentum transfer. This method has had a profound influence on the work of many authors in the past few years, and Dr. Mandelstam has published himself a number of investigations, some in collaboration with G. F. Chew, and others in which an attempt is made to derive from this a complete solution of the problem of the mutual scattering of π mesons, which from this point of view would seem to be the simplest problem in high-energy physics.

Applied Mathematics at Bangor :
Prof. D. R. Davies

Dr. David Rowland Davies has been appointed to the newly created chair of applied mathematics in the University College of North Wales, Bangor. Dr. Davies graduated in mathematics at the Imperial College of Science and Technology (University of London), where he afterwards studied for the degrees of M.Sc. and Ph.D. More recently, in 1958, he was awarded the degree of D.Sc. by the University of London. After a brief period as a meteorological officer in the Royal Air Force, Davies turned to university teaching as a career in 1946 and held posts at Liverpool, Southampton and Aberystwyth before taking a lectureship at Sheffield in 1949. He was there promoted to a senior lectureship in 1956 and appointed reader in applied mathematics in 1959. Davies has maintained his early interest in meteorology and is a Fellow of the Royal Meteorological Society and of the Royal Astronomical Society. His research interests have concentrated on atmospheric diffusion, evaporation from limited, saturated areas, and on heat-transfer in laminar and turbulent boundary layers, and he is the author of numerous papers on these topics. In Sheffield he has generated interest in this research, and his research students know him as a stimulating and enthusiastic, if demanding, leader ; at the same time, he is recognized as an inspiring teacher at the undergraduate level. As a Welshman by birth, it is not inappropriate that Davies should return to the Principality as the first holder of a new chair.

Zoology at the University of Leeds :
Prof. E. A. Spaul

Prof. E. A. Spaul, whose retirement from the chair of zoology in the University of Leeds takes place this summer, has been well known both in the North of England and in London for his active and valuable membership of many committees and examining bodies. He left school at the beginning of the First World War was commissioned, and remained on active service until 1918. He took part in many of the historic battles, and towards the end of the War he was transferred to gas warfare. After the War, he set himself the double task of graduating in zoology and at the same being a member of the teaching staff of the Zoology Department of Birkbeck College under Prof. Gordon Jackson. This was a time when interest in hormones was acute, and he ultimately gained his Ph.D. and D.Sc. for a study of pituitary action in amphibians. He was one of the first zoologists to move into the now active field of comparative endocrinology. He remained a member of the staff of the Zoology Department of Birkbeck College, rising to the position of reader, until 1933, when he was appointed to the chair of zoology in Leeds. While still retaining his interest in endocrinology, he then turned his attention mainly to teaching, to administration and to the encouragement of research by the younger people in his Department. In addition, he always encouraged sport, particularly rugby and hockey, among the students. He himself in his younger days was a brilliant rugby player, and recently he has for many years been chairman of the Committee in charge of the Leeds University Sports Grounds. Both he and his wife, who has also been most active on a variety of committees, will be greatly missed in Leeds.

Dr. J. M. Dodd

Dr. J. M. Dodd, who will succeed Prof. E. A. Spaul at Leeds, was educated at the White House School, Brampton, in Cumberland, and at the University of Liverpool. After graduating in zoology in 1938, Dodd taught for a short time at Cardigan Grammar School, and thereafter was on active service in the R.A.F. during the War. At demobilization, Dodd went as assistant lecturer to the Zoology Department of the University of Aberdeen, and here he came in contact with the Hogben school of comparative endocrinologists ; Dodd's own work in this field stems from this time. A year later, in 1947, the late Sir D'Arcy Thompson appointed Dodd as lecturer to the Zoology Department of the University of St. Andrews, his particular charge being to resuscitate the Gatty Marine Laboratory, which had been asleep for the previous thirty years. From 1947 to the present date, Dodd has worked in St. Andrews, being appointed reader in zoology in 1957 and director of the 'Gatty' in 1959.

ed Kingdom), the newly
na, Liberia, Guinea and
the Cameroons. The Scientific Council/Commission is financed by the member Governments on a percentage basis, each in its own currency, the United Kingdom and France contributing the biggest percentage (just under 20) of the total cost in 1960 of about £250,000, which is distributed over some fifteen separate budgets. Dr. Verdier testifies that whatever else the Scientific Council has accomplished in the ten years of its existence, in spite of rapid changes in Africa, it still provides a common meeting place where representatives of its member Governments, whether scientists or not, can discuss technical matters of importance to the continent of Africa without being hampered by other considerations which often make international co-operation so difficult.

The International Council of Scientific Unions

The Year Book of the International Council of Scientific Unions for 1960, besides a Calendar of Arrangements for 1960, lists the staff of the Secretariat, members of the Bureau and the Executive Board, as well as the National and Scientific Members of the Council and the countries adhering to the Unions (Pp. 109. The Hague: International Council of Scientific Unions, 1960). Details are also given of the membership of the special committees, joint commission, and executive bodies of the permanent services of the International Council. With the statutes and by-laws of the Council, the rules and charters for the special committees and permanent services, the particulars of the commissions of the Unions, of the relations of the Council with the specialized agencies of the United Nations, the list of addresses of international organizations, and the alphabetical list of members of the joint commission and other organizations of the Council and of the officers of the Scientific Unions, the Year Book is a most useful reference work for scientists and others engaged in international scientific activities. The Treasurer's report and financial statement issued as a separate paper show an excess of income over expenditure for the year ended December 31, 1959, of 17,568 dollars (Pp. 12. The Hague: International Council of Scientific Unions, 1960).

Irrigation in Great Britain

The second report to the Central Advisory Water Committee of the Sub-committee on Growing Demand for Water must be one of the shortest official reports on record (Pp. 5. London: H.M. Stationery Office, 1960. 6*d*. net). Extending to two pages only, the first deals with the appointment and terms of reference of the sub-committee and explains that the document is an interim report on uncontrolled abstractions of surface water, with special reference to irrigation water for agriculture. The second page proposes the early introduction of a temporary method of control through the river boards in view of the risk that growing abstractions will seriously deplete the natural flow of rivers at the time when they will be at their lowest levels. A detailed report is promised at some future date on the ultimate method of control, and this will doubtless reveal a selection of the data which has led to the early publication of the sub-committee's conclusion. While the sub-committee also recognizes that ultimately "provision should be made for conservation and storage so that water would be available for all legitimate purposes", the urgency of this need is only being realized slowly in Great Britain. So far H.M. Central Advisory Water Committee has only been prepared to look forward as far as 1965. In contrast, the United States Select Committee on National Water Resources is evaluating water needs for 1980 and beyond to the year 2000 on the basis of low, medium and high-level population increases.

If British national policy is to secure the maximum food output from the agricultural industry, farmers in south-east England should be actively encouraged, rather than discouraged, to irrigate; and although some form of temporary control of abstractions may now be advisable because of lack of foresight in the past, the time has surely arrived when a much more positive approach to the whole question of water conservation and supply in Great Britain is desirable so that the maximum benefit may be derived from the ample precipitation available.

Optics and Spectroscopy

Optics and Spectroscopy is now added to the list of full English translations of Russian scientific journals; it is published in the United States on the initiative of the Optical Society (6, No. 1. Translation of the Russian journal *Optika i Spektroskopiya*. Pp. iv+84. Published monthly. Subscription rate 25 dollars plus 3 dollars for postage. This rate includes the Journal of the Optical Society of America. New York: American Institute of Physics, 1959). This gives a welcome guarantee of the standards to be adopted. Five volumes of the original, in Russian, have already appeared, and the translations of the sixth and subsequent volumes will only be available as a joint subscription with the *Journal of the Optical Society of America*. In both the five previous volumes in Russian and the present translated issue, the coverage of the journal has corresponded quite closely with that of the *Journal of the Optical Society of America*, except for a surprising absence of papers on instrumental optics, diffraction and coherence problems. On the other hand, atomic and molecular spectroscopy, luminescence and optical properties of materials are all fully represented. From many sources it is known that very extensive work in instrumental optics is done in the Soviet Union, and it would be of great benefit to both optics and physics generally if the relevant publications were not only made known but also published in translation. It is not stated whether separate reprints of these translations will be sold. If not, it is to be regretted, for both the content of the papers in the present issue, and the excellence of the translations, will create a demand for them.

Bibliography of Indian Scientific and Technical Publications

In connexion with an exhibition in February 1960 of scientific and technical books published in India, organized by the Council of Scientific and Industrial Research, India, the National Library, Calcutta, has compiled a bibliography of Indian Scientific and Technical Publications (Pp. xii+195. New Delhi: Council of Scientific and Industrial Research, 1960. Rs. 25). The bibliography is based mainly on publications supplied in response to requests addressed to publishers, universities, research institutions, etc., and supplemented from information or material in possession of the National Library. Resources for compilation of a bibliography in the usual way were not available and it is proposed to supplement the present bibliography by such a compilation later. The present material is in two parts, the first containing the entries in the Indian languages, and the second the entries in English. Publications are arranged according to the Dewey Decimal Classification, and there is a consolidated subject index to both parts and separate alphabetical author indexes to each part. Of the English publications, 493 relate to agriculture, 315 to engineering, 119 to mathematics, and 100 to physics

The South African Museum

The *Annals of the South African Museum*, Vol. 45, Part 3, contains Part 5 of Prof. J. H. Day's detailed work on the polychaete fauna of South Africa. The present contribution deals with errant species dredged off the Cape coasts and is the first account of those organisms which occur below tide-marks. The prime object of this dredging survey is to determine distribution patterns around the southern part of Africa. Both the Hydrographic Section of the South African Navy and the Lamont Geological Observatory have provided facilities for the collection of material, though the bulk was obtained by members of the Department working from small boats during university vacations. The paper is illustrated with text figures.

Preservation of Films of Historical Value

The National Film Archive, created twenty-five years ago to undertake the permanent preservation of selected moving pictures of historical importance, either as works of film-art or as records of the life of our time, has now issued Part II of its published catalogue, "Silent Non-Fiction Films 1895–1934", to which Sir Arthur Elton contributes a foreword (British Film Institute. National Film Archive Catalogue, Part 2. Pp. x+195+12 plates. 15*s*.). The first volume ("Silent News Films, 1895–1933") was published in 1951, and a third, devoted to silent fiction films, is in preparation. The 1,054 entries are arranged chronologically under the country of origin, using wherever possible the date of release and the original release title, and the length and a short synopsis are also given. The great majority—727—of the entries are from Great Britain, and there is also an alphabetical index to film titles and a subject index.

The Archive, which is financed out of the Government grant made annually to the British Film Institute and administered by a committee appointed by the Governors of the Institute, has also issued a booklet describing the work of the Archive (The National Film Archive. Pp. 16. London: British Film Institute, 1960. 2*s*. 6*d*.). This has now built up a collection of 6,000 films, apart from newsreel material, covering the period 1895 to the present day and representing the work of more than thirty countries. Individual *bona fide* students engaged in some approved work or research may view preservation copies on an "Editola" in the Archive's premises under the supervision of the Archive's staff, and, with permission of the owners and under such conditions as they may stipulate, certain films may be shown in the National Film Theatre of the British Film Institute. Where the owners of historically important films are willing to allow them to be used for study by schools, universities, adult education groups and film societies, duplicate copies are made for hire through the British Film Institute's distribution service, and more than 200 films are available for distribution in this way. It is emphasized that the National Film Archive is a national film museum,

Rock Shelter Paintings near Bauchi in Northern Nigeria

During an investigation in the area around Geji, not far from Bauchi, Hamo Sassoon, deputy director of the Nigerian Department of Antiquities, found several painted rock-shelters. Of these the most important was near Geji itself. Four styles of painting were determined: there is a naturalistic style, the painting being made in solid red pigment; two series in a more diagrammatic style; and another series once again in solid red pigment, but much less naturalistic than the first. Antelopes, cows, monkeys, men and a horse are depicted. This last, which occurs in one of the diagrammatic series, is important, as it would seem that the horse would not have been known at Geji before about A.D. 1500. Only two superpositions can be observed and they happen not to be very helpful. It is not, then, possible to determine the relative ages of the four series, and as to an absolute date one can only say that one of the diagrammatic series cannot be earlier than A.D. 1500. Although the drawings are protected from the weather by an overhanging rock, it is very unlikely that any rock-shelter paintings can be of any vast antiquity. Precipitation and subsequent evaporation degrade the walls and any paintings tend to disappear. Only in deep caves, where conditions have not changed for long periods, can one expect survival. But the newly found paintings in Nigeria are of considerable interest. The local inhabitants have no idea who made them, but they do attribute magic qualities to them.

Relaxin

In a paper presented before the American Society of Biological Chemists in Atlantic City, N.J., Edward H. Frieden, of the Arthur G. Rotch Laboratory, Boston, Mass., has reported his analyses of relaxin (United States Department of Health, Education, and Welfare: Public Health Service. Publication No. 739: Highlights of Research Progress in General Medical Sciences, 1959. Pp. v+23. (Washington, D.C.: Government Printing Office, 1960.) 15 cents). Relaxin is secreted by the ovaries and apparently serves to relax the uterus during childbirth. Previous work by Frieden had indicated that relaxin was composed of a single molecular series; he now suggests that there are three components. The relaxin preparations, isolated from the ovaries of pregnant sows, were separated in a solvent system of 2-butanol and 0·2 per cent trichloracetic acid. A total of 355 transfers was made, with the relaxin compounds spread rather uniformly over 50 tubes. Pooled material from this distribution was re-run in the same solvent system, separating the three components. The amino-acid contents of the components were determined by paper chromatography of their acid hydrolysates and were found to be qualitatively identical. They included cystine, aspartic acid, glutamic acid, glycine, serine, histidine, lysine, arginine, alanine, valine, theonine, leucine and *iso*leucine.

U.S. National Centre of Atmospheric Research

Dr. Walter Orr Roberts, of the High Altitude Observatory, Boulder, Colorado, has been appointed director of a (U.S.) National Centre of Atmospheric Research. The National Science Foundation has granted 500,000 dollars to the University Corporation on Atmospheric Research to assist in establishing the Centre, which will consist of a central scientific group to stimulate and supplement university research. It will also provide facility management for what may become a large and widely dispersed research effort. Research programmes to be undertaken by the group will probably fall into four categories: atmospheric motions, energy exchange processes in the atmosphere, water substance in the atmosphere, and physical phenomena in the atmosphere. It is probable, however, that the staff will require about a year of investigation and exploratory work before deciding upon specific long-term research projects.

Oliver Memorial Fund Award

The Committee of the Oliver Memorial Fund has announced that it intends making its fourteenth annual award of the value of £50 to a British subject whose original work, or services in connexion with blood transfusion, is considered to be a notable contribution to the research, organization or donor aspect of this subject. Applications and communications directing attention to suitable candidates should be submitted before September 30, and should be sent to the honorary secretary, Mrs. F. E. Bedborough, 105 New Park Avenue, London, N.13.

University News : London

The title of professor of physics in the University of London has been conferred on Dr. E. H. S. Burhop in respect of his post at University College.

Queen Elizabeth College has received a grant from the Leverhulme Trust Fund of £3,800 over a period of two years to enable a sociological research programme to be started in the Department of Nutrition. The work will be carried out by Dr. Paul Morpurgo, who has been appointed Leverhulme Research Fellow in the Sociology of Nutrition for two years as from October 1.

A Wellcome Research Fellowship has been awarded to Dr. Angela E. R. Taylor to enable her to undertake in the Department of Biology research on the metabolic requirements of helminths, using radioactive tracers.

The London Research Foundation is making a grant to Queen Elizabeth College of £56,000 over a period of seven years to further the research work of the Department of Nutrition, with special reference to its work on fertility control.

Announcements

Dr. J. M. Winterbottom has been appointed director of the Percy Fitzpatrick Institute of African Ornithology as from September 1. The new building, on the campus of the University of Cape Town, which is to house the Institute, is now completed.

The Roentgen Prize of the Justus Liebig University of Giessen has been awarded to Mr. J. B. Adams, acting director-general of CERN (Geneva) and director of CERN'S proton synchrotron division.

The Langley Medal of the Smithsonian Institution, Washington, has been awarded posthumously to the rocket pioneer, Dr. Robert H. Goddard, who died in 1945, for the rocket experiments he started half a century ago at Clark University.

The Warner Memorial Medal of the Textile Institute has been awarded to Prof. C. S. Whewell, professor of textile technology in the University of Leeds. The Warner Medal is awarded in recognition of outstanding work in textile science and technology, the results of which have been published, and particularly for work published in the *Journal of the Textile Institute*.

The Science Museum Library has recently been presented with a collection of Japanese scientific and technical books and dictionaries on behalf of the Prime Minister of Japan, Mr. Nobusuke Kishi. The Library, as the result of this presentation, now possesses a very complete collection of such recent books in English or with English summaries, in addition to a large number of current Japanese scientific and technical periodicals.

The Faraday Society is organizing a general discussion on "The Physical Chemistry of Aerosols", which will be held at the University of Bristol during September 13–15. Further information can be obtained from the Assistant Secretary, Faraday Society, 6 Gray's Inn Square, London, W.C.1.

The eighth International Congress of Blood Transfusion is to be held in Tokyo during September 12–15. Further information can be obtained from Tomio Ogata, Blood Transfusion Research Laboratory, Japanese Red Cross Society, Shibuya, Tokyo.

La Società Italiana di Fisica is organizing an International Summer Course on "Solid State Physics" at the 'Centro Studi Nucleari di Ispra' during September 5–24. Further information can be obtained from Prof. G. Polvani, Società Italiana di Fisica, Via Saldini, 50, Milano.

The tenth International Congress of Applied Mechanics will be held in the Congress Building at Stressa during August 31–September 7. Further information can be obtained from the Secretary of the International Committee, Prof. Mekelweg 2, Delft.

An International Congress for Logic, Methodology and Philosophy of Science will be held at Stanford University, California, during August 24–September 2, under the auspices of the International Union for History and Philosophy of Science. Further information can be obtained from Prof. Patrick Suppes, Serra House, Stanford University, Stanford, California.

The fifth International Congress on Nutrition will be held in Washington, D.C., during September 1–7, and will be organized under the auspices of the International Union of Nutritional Sciences, the American Institute of Nutrition and the U.S. National Committee, International Union of Nutritional Sciences of the National Academy of Sciences–National Research Council. Further information can be obtained from the Secretariat of the Congress, 9650 Wisconsin Avenue, Washington 14, D.C.

The Extra-mural Department of the University of Manchester, on behalf of the Department of Physics of the Manchester College of Science and Technology, is holding a summer school in Modern Methods of Crystal Structure Determination during August 29–September 9. The school has been arranged to follow the meeting in Cambridge of the International Union of Crystallography. Further information can be obtained from Prof. H. Lipson, Manchester College of Science and Technology, Sackville Street, Manchester, 1.

rivalry, and who, by their experience and special knowledge, are best able to suggest remedies.

The officers of the national groups meet several times each year at various international centres, and the Association discusses the problems arising at congresses held in alternate years, different countries acting as hosts. Since the War, the Association has held congresses at The Hague (1947), Paris (1950), Vienna (1952), Brussels (1954), Washington (1956), Stockholm (1958), and now London (1960). The previous congresses held in London were in 1898, 1912 and 1932. Prior to the Second World War, the congresses were rather small affairs, but international interest in industrial property has grown so considerably that attendance and the number of countries interested have increased greatly. At the recent congresses, about 600 delegates have attended, with their ladies. In London, the number increased still further to about 700 and the total of participants (including ladies) was more than 1,400, representing thirty-eight countries. There were representatives from the Governments of sixteen countries, five intergovernment organizations and four international associations. The Government representatives were mostly heads of national patent offices and ministries corresponding to the Board of Trade in Britain.

The London Congress was held under the patronage of H.R.H. Prince Philip, and under the presidency of Sir John Hanbury-Williams.

At the working sessions, held in St. Pancras Assembly Rooms, simultaneous translation of papers in English, French and German was arranged. The following problems were discussed: termination of rights to register trade marks owing to non-use; cancellation of the registration of a trade mark at any time upon proof of abandonment; trade marks or trade names with extended protection; suppression or limitation of trade mark rights after a certain period of use; revocation of patents for non-working; effects on industrial property rights of national and international rules providing for free competition; competence of arbitrators and enforcement of their awards in matters of contracts relating to industrial property; method and preparation of a study of the unification of patent laws; restrictions of the right of the patentee for reasons of public interest; temporary protection at exhibitions; extension of periods expiring on a public holiday; international protection of works of applied art, designs and models; revision of the "Arrangement" of The Hague concerning the international deposit of industrial designs and models; licensing of trade marks; translation of trade marks.

All these problems were fully and freely discussed by the delegates, and in due course the recommendations of the Congress on them will be published and submitted to the Bureau of the Industrial Property Union for the next diplomatic conference, which, so far as The Hague "Arrangement" for industrial designs and models is concerned, will be held at The Hague in November next.

On the social side of the congress week, the inaugural ceremony of its opening was held at the

Royal Festival Hall on May 30, presided over by the Lord High Chancellor, the Right Hon. the Viscount Kilmuir; on May 31, a Government reception was held at Lancaster House under the auspices of the Board of Trade, which was also attended by Prince Philip; on June 2 the delegates attended a gala performance of "The Barber of Seville" at the Royal Opera House; and on June 3 the closing banquet was held in the Great Hall of the Royal Courts of Justice (by permission of the Lord Chancellor and the Minister of Works), followed by a ball in the Halls of the Middle and Inner Temples (by permission of the Benchers of the Middle Temple and Inner Temple).

In consequence of the earnest representations of the German Group, it was agreed that the next Congress of the International Association for the Protection of Industrial Property be held in Berlin in 1963. The Japanese Group also made strong representations that the Congress following the Berlin one be held in Tokyo in 1966, especially as the Association has never yet met in Asia. In view of the decision to hold the next Congress in Berlin, an invitation was sent to Peter von Siemens, of Werner von Siemens, Erlangen, to succeed Sir John Hanbury-Williams as president.

The permanent officers of the International Association are: *Secretary-General*, Eugène Blum; *Assistant Secretary-General*, Dr. Rudolf Blum, of Zurich, the headquarters of the Association. *Reporter General*, M. Paul Mathely (Paris); and *Treasurer General*, M. Jaques Bede (Brussels). The president of the British Group is Mr. G. W. Tookey, Q.C., the joint secretaries, Mr. Michael Hesketh-Prichard (chartered patent agent) and Mr. Martin H. Lowry (solicitor), and the treasurer Mr. L. A. Ellwood (solicitor). The president of the German Group, which will be responsible generally for the organization and running of the next Congress, is Herr H. G. Heine (patent agent), and the secretary, Herr Moser von Filseck (advocate).

H. C. MILLER

PARASITES AS ENEMIES AND ALLIES

THE Spring Meeting of the Parasitology Group of the Institute of Biology was held during April 6–8 in the new buildings of the Liverpool School of Tropical Medicine, by kind arrangement with Prof. W. E. Kershaw. This was the second annual meeting of its kind, and was attended by about a hundred biologists with widely differing interests in parasitology.

Twenty offered papers were concerned with a variety of disciplines and of animal parasites, ranging from studies on the biology of the tapeworm larva, *Cysticercus bovis* (P. H. Silverman), to mitochondrial enzymes in relation to malaria (B. G. Maegraith) and a mathematical analysis of populations of helminths in wild and domesticated animals (H. D. Crofton). The invited speaker, Prof. T. H. Davey, surveyed the role and status of parasites in his discourse on "Parasites as Enemies and Allies".

In the rapidly developing field of physiology of parasites, R. L. Muller presented his experiments on glycogen metabolism in *Haplometra cylindracea* and showed this fluke to be an obligate aerobe—a nice correlation with its habitat in the lung of the frog. Investigations into the growth patterns of certain tapeworms, undertaken by C. A. Hopkins, revealed that during growth the plerocercoid larva doubles its weight every 24 hr., and that it becomes infective before reaching its maximum size. Under the stimulus of transmission to the definitive host, exponential growth is resumed until maturation of the worm. Hopkins suggested that at maturation a growth-inhibiting substance is produced which, because of linear growth and the lack of a circulatory system, does not affect the anterior region of the worm. The proteolytic activity of extracts prepared from *Entamoeba histolytica* and the optimum conditions for proteolysis were reported by R. A. Neal.

Histochemical studies included the distribution of nucleic acids in normal and in akinetoplastic strains of *Trypanosoma evansi* by J. R. Baker. D. L. Lee showed that the ovijector of *Thelastoma bulhoesi*, a nematode inhabiting the hind-gut of the cockroach, secretes a mucoprotein responsible for the sticky covering of the eggs. Certain aspects of the behaviour of parasites were treated by F. Hawking and M. J. Worms, who described responses of microfilaria counts of *Monnigofilaria setariosa* to external stimuli applied to the host, the mongoose, and who discussed reasons for the periodic migrations of microfilariae into the peripheral blood.

A knowledge of the life-cycle of a parasite is fundamentally important to epidemiological studies of parasitic diseases, and work by T. E. Gibson on the development of eggs and larvae of two species of sheep nematode, *Nematodirus battus* and *N. filicollis*, and on pasture population densities has allowed grazing management methods to be devised which enable complete control of the disease. The density of parasite populations is also important in the case of ducks harbouring the acanthocephalan *Polymorphus minutus*, which under certain conditions can cause serious losses, and H. B. N. Hynes gave an account of the way in which the parasite spreads by means of its intermediate host, *Gammarus* spp., from an infected flock penned on to a small stream.

An example of how a population of parasites may serve as an indicator of different zoogeographical populations of host was illustrated by Z. Kabata. Whiting inhabiting the North Sea to the north of the Dogger Bank harbour abundant *Ceratomyxa* in the gall bladder, whereas fish to the south are infected with *Myxidium*. There are also differences in the myxosporidian fauna of these fish from the Faeroes and of the haddock from these areas.

Parasitic infections may evoke immune reactions in the host, and this host-reaction can be utilized to test for the presence of the parasite. R. J. Terry, D. Poynter and P. H. Silverman reviewed and appraised the value of various haematological and serological techniques employed in diagnostic tests. Further uses of host-reaction in detecting the presence of a parasite were reported by S. F. M. Davies and L. P. Joyner, who found that in chicks with a sub-lethal

chrysanthemum in susceptibility to attack by eelworms were discussed by H. R. Wallace. The behaviour of eelworms on the outside of the plant, the invasion of the leaves through the stomata and movement of the worms within the leaf were described. The evidence supports the theory that varietal variation in susceptibility is related to hypersensitivity of the leaf tissues to eelworm invasion.

The degree of host-specificity shown by a parasite may be important in the epidemiology of human disease, as in the case of a pathogen harboured by both man and his domestic animals. F. E. G. Cox posed the question, "Is *Balantidium coli* a zoonosis ?" and presented data suggesting that this protozoan normally found in pigs is not, contrary to common belief, easily acquired by man except possibly in certain nutritionally deficient states. Another group of protozoans, the 'Limax' *Amœbae*, have frequently been reported as parasites of both invertebrates and vertebrates, including man, and they are also abundant in the soil. Although these animals are similar morphologically they show great differences in their physiology and micro-anatomy and these differences are reflected in the ecology of the individual species. K. Vickerman submitted evidence that some of these 'Limax' *Amœbae* are facultative parasites closely related to soil-occurring forms, whereas others are obligate parasites more closely resembling the Endamoebidae.

A group of short papers and demonstrations described the work in progress at the Liverpool School of Tropical Medicine, and these together with three other laboratory demonstrations concluded the meeting. The proceedings of this meeting will not be published in full.

lding ability, but it is

hoped they will prove valuable to the grower as a means of producing better quality fruit.

The main variety trials were concerned with the further evaluation of selections descended from hybrids with the compact-habit (short internode) 'Baby Lea' variety, and include some which have attracted a good deal of interest among growers. Some of this material is being subjected to wide screening on growers' holdings and experiment stations this year.

Of interest in connexion with the tomato-breeding programme and other work at the Institute was a demonstration by the statistician (Mr. D. Cooke) of the results of a survey carried out in 1959 of the varieties of tomato grown commercially. From a 10 per cent sample of growers seventy distinct varieties were recorded, the four most commonly grown, according to total acreage, being 'Moneymaker', which occupied 32 per cent of the 2,067 acres estimated to have been grown in Great Britain in 1959, 'Potentate' (17 per cent), 'Ware Cross' (15 per cent) and 'Ailsa Craig' (6 per cent). Within this general pattern, however, there were marked differences according to district and time of planting.

The Chemistry Department, under Dr. G. W. Winsor, demonstrated some aspects of its work on plant nutrition, composition and biochemistry. The nutrition trials now cover the tomato, carnation, lettuce and early-flowering chrysanthemums, and the Department is closely associated with studies on bulb nutrition at the Ministry of Agriculture's Experimental Husbandry Farm at Kirton, in Lincolnshire. The special demonstration for the day was on the subject of carnation nutrition, the first experiment, extending over two years, having just been completed. This factorial trial, testing three levels of nitrogen and two of potash in the presence or absence of added phosphate, magnesium or calcium, making forty-eight different combinations of fertilizer treatment in all, showed a beneficial response to phosphate and nitrogen in terms of total flower production, and splitting of the calyces was more marked at low nitrogen-levels. A more complete assessment of the results will be possible when the numerous soil and tissue samples taken during the course of the experiment have been analysed. Visitors were able to see the second experiment on this subject which had just been planted; this is another factorial trial comprising four levels of nitrogen and three levels of potash supplied in liquid feeds, superimposed on four levels of phosphate and two levels of lime incorporated in the planting compost.

Other subjects dealt with by the Chemistry Department were the problem of manganese toxicity and the effect of soil salinity on plant growth. Symptoms of manganese toxicity had been observed on tomato, carnation and lettuce, and the disorder appears to arise when considerable amounts of soluble and exchangeable manganese are released from glasshouse soils sterilized by steaming. For the soil salinity studies a reliable and convenient method for the fairly rapid determination of salt concentration in the presence of sparingly soluble salts such as calcium sulphate, which commonly accumulate in glasshouse soils, is being sought.

The Chemistry Department is devoting a good deal of attention to studying the composition of tomato fruit. Rapid methods have been developed for the analysis of relatively large numbers of fruit samples, and much information is being accumulated on the relation between fruit composition and manurial levels, variety and environmental conditions. Special attention is being paid to the problems of fruit quality in relation to fruit composition, and it is hoped that the information being obtained will serve as the basis of an approach to the problem of fruit flavour. Although there is much still to be learned as to the primary cause of fruit disorders, such as 'blotchy ripening', it is clear that their development ultimately depends on some departure from the normal biochemical processes of fruit ripening. Studies of certain enzymic processes in tomato fruit have therefore been undertaken, starting with the pectic enzymes associated with the softening of tomato fruit during ripening. Limited exploratory work on the effects of ripening of certain enzyme inhibitors injected into tomato fruit is also in progress, the object being to gain some insight into the mechanisms by which rates of ripening are controlled in the fruit.

The environmental factors which influence ripening disorders in the tomato fruit have also been investigated by the Plant Physiology Department, under Dr. E. R. Leonard, and experiments were shown in which the effects of subjecting fruit tissues to different levels of temperature, while the plants remain at house temperature, were being studied with particular reference to fruit coloration.

Work on the growth of the tomato has been carried a stage further, and plants were seen growing in glass chambers in which the environment, including day-length, is partially controlled. Weekly measurements of roots, stems, leaves and fruit were being made on these plants, as well as daily counts of anthesis. In an accompanying experiment the relation between growth and development of tomato plants and the age of the plant and time of year was being further investigated, with special reference to the development of the first truss.

Work on virus diseases was a particular feature of displays by the Plant Pathology Division, under Dr. L. Broadbent. A number of diseases of flowers and ornamentals which are being studied were demonstrated, as well as attempts to free stock plants of chrysanthemum and carnation from virus diseases by heat therapy or meristem culture. The investigation of tobacco mosaic virus on the tomato, a serious problem to the grower, has been intensified, and several critical experiments on various aspects of the problem were in progress. Special attention is being paid to the sources of infection in commercial glasshouse practice, and experiments are being carried out to determine the relative importance of seed, infected residues in the soil, infected structures and tools, infected clothing and smoking tobacco. An attempt is also being made to assess the loss from infection under glass, using a moderately severe strain of tomato mosaic virus inoculated into two varieties, 'Potentate' and 'Moneymaker', at three stages in plant growth. The experiment was planted in mid-February, and by the open day there were marked differences in growth and fruit set between early-infected plants and the remainder, all the inoculated plants being still healthy.

Also within the programme of the Plant Pathology Division was a demonstration of the work on the 'watery stipe' disease of the cultivated mushroom, undertaken in the Mycology Department under Mr. P. H. Williams. Recent experiments have shown beyond doubt the transmissibility of this disease, and the infective principle in a diseased mycelium, which is always characterized by abnormally poor growth, can be passed to a healthy one simply by growing the two together. The further finding that infectivity can be eliminated from diseased cultures by a process akin to heat therapy raises the intriguing possibility that a virus may be responsible for the mushroom disorder, and virological techniques are being employed with the view of finding out if this is so.

Other work on cultural aspects of the mushroom is undertaken by the Horticultural Department under Mr. G. F. Sheard, and specially constructed chambers for studying the effect of environmental conditions on fruiting and development of the mushroom were on view. In these chambers, of which there are eight, each with 4 sq. ft. of growing area, temperature, relative humidity and ventilation-rate can be varied independently.

Among crop protection problems under study was a comparison of chemical soil sterilizing agents, including the newly introduced metham-sodium (sodium methyldithiocarbamate), with the traditional steaming method. This experiment has shown that on a soil free from serious soil-borne diseases, yet needing sterilizing to restore fertility, chemicals can be as effective as steaming, treated plots giving about a 20 per cent increase in crop over the untreated controls. under Mr. W. H. Read, and the Entomology Department, under Dr. N. W. Hussey. This work involves the testing of Lea Valley strains of the mite for cross-resistance to other acaricides to assess the practicability of increasing the range of materials in use. This is to be followed by large-scale trials later this year to investigate control of the pest by physical and biological agencies to which it is unlikely to develop resistance.

ence was being taught

in secondary modern schools, 47 per cent are obliged to teach all or part of their science under unsatisfactory conditions.

The investigation revealed that only one science teacher in six in a secondary modern school is a graduate, while about one in six has "no pretensions at all to science qualifications". Only 34 per cent of the schools considered that they were adequately staffed for teaching science. Special account is taken in the survey of head teachers' opinions on the most important needs to improve science teaching. Their orders of priority are more science teachers, more laboratory accommodation, and more equipment.

The statistical return suggests that, in 65 per cent of the schools concerned in the survey, more science staff are needed. The booklet comments: "It follows that in the country as a whole no fewer than 2,500 schools need science teachers and in some cases more than one teacher will be required".

Copies of the booklet are available, price 1*s*., from Mr. D. M. Chillingworth, The Village College, Swavesey, Cambridgeshire.

officers from 28 to 23 and of scientific assistants from 20 to 14, chiefly in the Divisions concerned with soil fertility, soil chemistry and soil classification, with the result that the Organization is not always able to co-operate effectively with the Territorial Departments. The Trypanosomiasis Research Organization also refers to reduction in staff, and the Meteorological Department has found the difficulty of recruiting staff from Britain to constitute a formidable obstacle in its programme of expansion. On the other hand, help is being received from the Rockefeller Foundation for agricultural research in East Africa, and the Nuffield Foundation is financing further research on the physiology of drought resistance in crops, and on the improvement of the nitrogen status of tropical soils by suitable use of indigenous tropical legumes.

The work of the Agriculture and Forestry Research Organization has included work on the increase of crop-yields by reducing the damage done by pests and diseases, such as the study of 'stem pitting' of *arabica* coffee, a survey of the nematodes of the principal East African crops, the development of a strain of maize resistant to the virus disease known as 'streak', and also work on the effect of drought on the growth of plants and the water requirements of irrigated crops. Forestry research also has been concerned with the effect of forests on water supplies, as well as the best methods of raising seedling trees in the nursery and for planting out in the forest, and the protection of East African forests against insect attack, particularly by timber borers, and the use of ultrasonic and gamma-radiographic techniques to detect attack and to measure the severity of attack are being examined. In the Veterinary Research Organization, the Division of Virus Diseases achieved interesting and important results in its investigation of rinderpest. Good progress was made in research on swine fever, and work on East Coast fever continued; but the work of the Division of Bacterial Diseases was hindered by shortage of staff.

* East Africa High
100. (Nairobi: Gov

nual Report, 1959. Pp. iv+
960.) Sh. 5.

The reorganization of the East African Trypanosomiasis Research Organization is well advanced, and all research disciplines are being concentrated at Tororo in Uganda. Studies on the trypanosomes are being developed mainly towards an understanding of immunology and the routine testing of new drugs for cattle prophylaxis is now to be the concern of the Territories, and the Research Organization is recruiting workers for fundamental studies on drug resistance. The Marine Fisheries Research Organization continued its work on tuna longlining and the North Kenya banks survey, and an investigation of the potential prawn fishing of the estuarine waters of Tanganyika was commenced.

The Pare–Taveta malaria scheme of the East African Institute of Malaria and Vector-borne Diseases, which ended in June 1959, has shown that malaria transmission can be reduced to a very low level but not completely arrested, as a result of four years residual spraying of houses, in an area of hyperendemic malaria. The dispersion and longevity of *Anopheles gambiae* were studied mainly by introducing radioisotopes into the larval breeding pans. The completion of the 120-ft. steel tower in the Mpanga forest enabled the Virus Research Institute to expand considerably its work on the biology of mosquitoes and other blood-sucking flying insects, and the analysis of data collected over the past fifteen years indicates that while in some species of mosquito the biting pattern is uniform over a very wide area, in others the pattern varies according to locality, environment or even level in the forest. The East African Leprosy Research Centre commenced a therapeutic trial of 'Etisul', and surveys of leprosy clinics in Uganda and Kenya confirmed the low proportion of true lepromatous cases.

The East African Industrial Research Organization completed its projects on the mechanical drying of coffee and on the control of arsenic in the production of cement copper. The Meteorological Department continued its investigation on the use of cetyl alcohol to reduce evaporation from water surfaces, and a two-year programme of forecasting research was commenced in June 1959 to gain knowledge of the rain-producing agencies operative in East Africa and the improvement of weather forecasting generally. Progress is being made in the study of the strong winds which occur at high levels in tropical and sub-tropical latitudes. The Desert Locust Survey reports on control operations against swarms in the Somaliland Protectorate, January–June 1959 and July–October 1959, and in Turkana, April–May 1959, and on campaigns against hopper of the short-rains generation in the Somali peninsula conducted in the Ogaden. Reference is made in the report to the problems created for the Directorate of Civil Aviation by the introduction of jet airliners and to the difficulty of recruiting suitably trained and experienced officers capable of maintaining standards

SUICIDE: A NEGLECTED PROBLEM

THE incidence of suicide is on the whole low in the less-developed countries, high in the more; and in some countries of very high living standards it has become a problem of considerable proportions. Between the ages of fifteen and forty-four it is the second most important cause of death in Japan, the third in Germany, Denmark, Sweden and Switzerland, and the fourth in Canada, Australia and the United States. It is also an important cause of death between the ages of forty-five and sixty-four*.

In the United States some 16,000 people commit suicide every year, as compared with 14,000 who die from tuberculosis and 40,000 who die from motor accidents; in England and Wales the number of suicides, approximately 5,000 annually, is nearly as great as the number of those who die from pulmonary tuberculosis, and slightly exceeds the number who die from motor accidents. More men commit suicide than women, and, as age increases, the preponderance of male suicides becomes greater.

Durkeim, in his classic study of suicide, divided suicide into three types: the altruistic, in which the individual's life is rigorously controlled by the customs and beliefs of a rigid society, and who commits suicide for religious or political reasons; the egoistical, in which he is insufficiently integrated into society; and the anomic, in which he is insufficiently regulated by society and his adjustment may be upset by economic catastrophes or sudden wealth.

Inherent disposition plays an important part in suicides. The stresses of loneliness and friendlessness act with selective severity on those predisposed to mental illness, and these are often the individuals who commit suicide. Cause and effect are not easy to distinguish. Do individuals, for example, who commit or attempt to commit suicide drift into isolated environments because of the illness that drives them to take their own lives, or are certain environments conducive to suicidal tendencies? Alternatively, is loneliness both a consequence of mental ill-health and a factor increasing the chances of suicide? The whole problem of suicide is extremely complex; the causes are not well understood.

Statistical data about suicide are among the most clear-cut epidemiological facts in the whole field of psychiatry, and should lend themselves to intensive inquiry. It might then be possible to understand more clearly why there are striking differences in incidence between the more-or-less developed countries, between communities of different religious denominations, and between urban and rural areas. It should then be possible to prevent attempts at suicide, and provide those who attempted but failed with efficient after-care or social support.

values for the r again over long periods
of time subseq s.

Study of the reduction, produced by ashing, of alpha activity due to the uranium series and of the rate of recovery of this activity during the succeeding months has provided valuable information as to the presence of specific members such as lead-210 and polonium-210 in many of the matt and vegetation specimens. Further evidence of the presence of polonium-210 has been provided by an alpha-ray spectroscopic technique^{4}. Serial measurements have, in addition, provided evidence of growth of alpha activity due to the thorium series in numbers of the specimens of vegetation.

Measurement of more than fifty specimens of soils, sands and chalks from different parts of Great Britain and from Central Africa revealed values of total alpha activity ranging over a factor of only 5 to 1 for soils and about 8 to 1 for sands.

Table 1 lists the values found for a few selected specimens including the maximum and minimum activities so far observed in each category. Assuming that radioactive equilibrium exists in both series, the soil uranium contents range from 0·5 to 2·3 and the thorium contents from 0·6 to 3·0 μμc./gm. soil.

Table 1. Soil Activities in μμc /gm. Raw Soil

Chalk 1	Surrey	0·9	0·06	0·06	1·0
Chalk 2	Kent	0·8	0·07	0·04	0·5

The values observed for chalks are relatively much lower, with little difference between specimens of different origin.

Six months or so after sealing the soil samples the majority showed small increases of 5–6 per cent in their alpha activities, presumably due to reduction of loss of radon and hence to a slight build-up of radon and the later members of the uranium series.

The specimens of raw matt showed initial values of total alpha activity ranging from 8 to 28 μμc. per gm. a few days after sealing, but in the subsequent months marked differences were observed between the behaviour of the various samples.

Table 2. Activities of Raw Matts in µµc./gm.

Ref.	Origin	T.A.A.		U-series		Th-series	
		$t = 0$	$t = 100$	$t = 0$	$t = 100$	$t = 0$	$t = 100$
*SA*1	Wales	13·0	13·0	4·8	—	8·4	—
*SA*4	Wales	11·0	12·3	9·4	10·5	1·8	1·8
*SA*6	Devon	28·0	31·1	15·0	18·1	13·0	13·0
*SA*12	Ireland	9·4	9·4	4·0	—	5·4	—
*SA*23	Berks	8·0	10·4	3·7	6·1	4·3	4·3
*SA*24	Berks	8·2	12·2	5·8	6·6	2·9	5·6

Table 2 gives the values of alpha activity and the relative contributions from the two natural series observed in a few of the specimens at time $t = 0$ (soon after sealing the sample) and 100 days later. Three types of behaviour are illustrated.

In samples *SA*1 and *SA*12 no change was observed in their activities after 100 days, whereas in *SA*4, *SA*6 and *SA*23 the total alpha activities rose, due to increased activity of the uranium series with the contribution from the thorium series remaining unchanged. In *SA*24 there is increased uranium series activity and an even more striking rise in activity due to the thorium series. Evidently the matts may have either or both of the two natural series in a state of radioactive equilibrium or disequilibrium, and the alpha activity of any particular specimen may vary appreciably with time after sampling.

An aliquot of *SA*4 matt showing increased uranium series activity with time was reduced to mineral ash in a muffle furnace and a series of measurements carried out on the ash during the following twelve months.

Table 3 summarizes the results of these observations. A concentration of 7·26 times was achieved by ashing, and the figures for the raw matt activity in column 4 have been derived by dividing the values of ash activity in column 3 by this factor. Column 2 gives the values observed directly on the raw matt sample.

Table 3. Recovery of Matt Activity after Ashing Specimen *SA*4

Days after sealing	Total alpha activity µµc. per gm.		
	Raw matt by direct measurement	Matt ash	Raw matt value from ash value and concentration
0	11·0	13·6	1·9
28	11·5	24·0	3·3
100	12·3	43·0	5·9
150	—	53·0	7·3
335	12·5	64·6	8·9

It will be seen that immediately after ashing the estimated alpha activity of raw matt as deduced from the ash value (column 4) was only 17 per cent of the value observed directly (column 2) for the raw matt. After 28 days when the radon, radium *A* and radium *C′* lost in the ashing process have recovered to equilibrium with the radium-226 present, the ash activity is still only 29 per cent of the expected value. The ash activity continued to increase and is still rising after 335 days from the time of ashing.

Using the ash activities of column 3 and assuming that the increase in alpha activity after 28 days is due to the growth of a single alpha emitter, it is easy to calculate that the half-life of this emitter would be about 150 days and we deduce that the nuclide concerned is almost certainly polonium-210. If this is the case, the final value which will be reached by the polonium-210 can be shown to be 78·0 µµc. per gm. ash and the equilibrium total alpha activity to be 92·7 µµc. per gm. ash. This latter figure corresponds to a raw matt activity of 12·8 µµc. per gm., which has very nearly been reached by the direct measurements on the raw matt given in column 2.

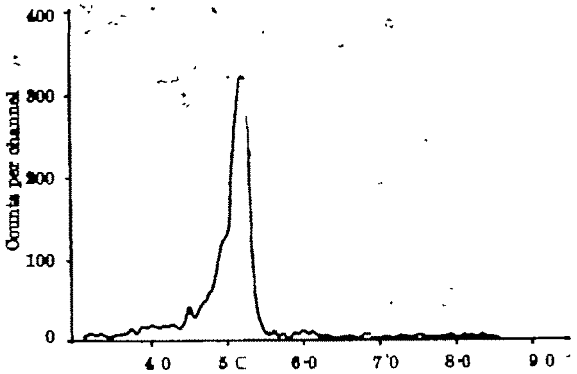

Fig. 1. Alpha-ray spectrum of *SA*4 matt ash

Furthermore, the constant portion of the activity of the ash after 28 days can be shown to be 14·7 µµc. per gm., of which 2·9 µµc. is due to radium-226. Hence the radium *D* (lead-210) content of the matt is a factor of 78·0/2·9, that is, 27 times higher than the radium-226 level.

In other words, 84 per cent of the alpha activity of this matt specimen is apparently due to the single nuclide polonium-210 existing in or near equilibrium with its parent lead-210, which itself is present at a much higher level of activity than radium-226.

Fig. 1 shows the alpha-ray spectrum of this particular matt ash and clearly indicates that a single alpha emitter is responsible for the majority of the activity and that its energy is approximately 5·3 MeV., the energy of the polonium-210 alpha particle.

Table 4. Grass Ash Activities in µµc./gm. Ash

Ref.	Origin	T.A.A.	Ra-series	Th-series
*SA*1	Wales	9·6	5·6	4·0
*SA*6	Devon	11·0	8·2	2·8
*SA*9	Scotland	21·0	16·0	5·0
*SA*12	Ireland	9·7	6·4	3·3
*SA*22	Berks	1·1	0·9	0·2
*SA*23	Berks	5·2	4·1	1·1
*SA*24	Berks	2·8	1·8	1·0
*D*69	Wales	67·0	64·0	3·0
*D*154	Wales	85·0	79·0	6·0

Table 4 lists the total alpha activities and the relative contents of the two natural series observed in specimens of grass ash made available to us many months after ashing. It will be seen that the total alpha activities range from 1·1 to 85·0 µµc. per gm. ash—a factor of almost 80 to 1. The higher values were found in specimens derived from Wales and Scotland, and in these cases the alpha activity is very largely due to the radium series which contributes up to 90 per cent of the total alpha activity.

It will be seen from comparison of Tables 1 and 4 that no simple relation is apparent between the natural activity of a particular specimen of grass and the activity of the soil in which it grows.

Table 5 gives the results of serial observations on six samples of grass ash at 30, 100 and 180 days subsequent to ashing. No evidence of change of thorium series activity was observed in these specimens, whereas the radium series content in each case

activity of different
e soil in which the

ses of alpha activity
mens of leaf ash, the
ical increases due to

the radium series and the remaining three due to the thorium series.

Assuming that the rise of activity of the radium series is due to the growth in activity of a single alpha emitter, the half-life of this nuclide has been calculated from the data of Table 7. The values are respectively 163, 139, 124 and 167 days with a mean half-life of 148 days. Once again there would appear to be little doubt of the phenomenon being due to the growth of polonium-210 to equilibrium with its parent lead-210.

The increases of thorium series activity appear to be linear up to the latest time of observation—300 days after ashing—indicating the growth of an alpha emitter the half-life of which is much longer than 300 days. The thorium series contains only three members with half-lives longer than 300 days, namely, the head of the series thorium-232, its daughter radium-228 (half-life 6·7 years) followed by thorium-228 (half-life 1·9 years). During the whole of our investigations on human, animal and plant tissues no evidence has yet been found, even by alpha spectroscopy, of the presence of thorium-232 in such materials.

In the absence of thorium-232 at a higher level of activity than its daughter radium-228, there remains only one possible explanation for the growth of activity due to the thorium series at the rates indicated in Table 7, that is, by the growth of thorium-228, and hence of all the subsequent short-lived members of the series, towards equilibrium with its parent radium-228.

If radium-228, not itself an alpha emitter, exists in the leaf ash at a level of activity higher than its daughter thorium-228, then the observed increases in thorium series activity are explained. This in turn implies that the plant takes up the radium isotopes in preference to thorium and is in agreement with our earlier findings for human and animal tissues and for plant foods. In all these cases the radium contents are invariably in excess of the thorium levels, in spite of the greater abundance of the latter in the soil.

One of the outstanding features of these observations is the very wide range of natural alpha activities found in vegetation compared with that in the corresponding specimens of soil. We recognize the

difficulty of obtaining representative samples of such materials; but it is clear that no simple general correlation exists between the plant and soil activities.

It has been interesting to observe the widespread and often predominant activity in vegetation due to polonium-210 which appears to be present in specimens ranging from British grasses to plants of various species from Central Africa. It is evident that this substance or one of its precursors such as radon-222 or lead-210 may be taken up directly from the soil. It has been shown by Jaki and Hess[7] that even moderate rainfall can restrict the rate of escape of radon-222 from the surface of the soil, and it is clear that in areas of high rainfall this factor could result in concentrations of lead-210 and in turn polonium-210 being produced in the top layer.

A linear relationship between the alpha activity of grasses and the annual rainfall has been demonstrated by our colleague, Mr. C. R. Hill[8], and suggests that polonium-210 or one of its precursors may also be taken up directly from rain. The relative importance of the contributions resulting from these two mechanisms presumably varies from site to site, depending on parameters such as species of plant, soil drainage characteristics, depth of the water table below the surface and probably many other factors.

The complexity arising from the evident preference of vegetation for radium rather than thorium isotopes together with uncertainty of the degree of radioactive equilibrium existing in the plant–matt–soil system at any particular time renders generalization dangerous.

We have so far little information concerning variation of the natural alpha activity of plant materials with season, rate of growth and many other parameters. It is clear that in order to define the alpha activity of vegetation on or near a given site, complex sampling procedures are necessary, followed by serial measurements spread over a considerable time.

We express our gratitude to the Westminster Hospital Medical School Expedition, 1958, for making available to us the range of soil and plant materials from Central Africa. We would also like to thank Dr. R. Scott Russell, director of the Radiobiological Laboratory of the Agricultural Research Council, for providing the numerous assay samples of soils, matts and grasses. Finally, we wish to thank our colleagues, Mr. C. R. Hill and Miss Mary Duggan, of this Department, for their assistance during these investigations.

LEAD-210 AND POLONIUM-210 IN GRASS

By C. R. HILL

Physics Department, Institute of Cancer Research
Royal Cancer Hospital, London, S.W.3

In recent publications from this Department[1,2] it has been shown that the α-activity observed in certain samples of grass is largely due to the presence of polonium-210 (radium *F*), accompanied by its parent lead-210 (radium *D*). In the present communication evidence is presented that suggests that a large part of such activity may originate as a decay product of atmospheric radon (Table 1), which is afterwards deposited on to the grass by rainfall.

Table 1. THE LONG-LIVED DECAY PRODUCTS OF RADON-222

Nuclide	Half-life	Mode of decay
^{210}Pb (Ra D)	22 yr.	$\beta\gamma$
^{210}Bi (Ra E)	5 day	β
^{210}Po (Ra F)	138 day	α
^{206}Pb	stable	

Samples of grass and topsoil were collected during the first week of December 1959 from twenty well-separated points in the southern part of Great Britain, chosen to provide a wide variety of soil and rainfall conditions. Total α-activity measurements[3] were made on the dried grass and soil samples and also on a number of grass ashes. Observation of the build-up of polonium-210, following its volatilization on ashing, has confirmed that the α-activity measured in the grass samples was again due mainly to this nuclide. A similar increase in α-activity with time was observed in the case of the unashed dry grass samples, but from a relatively higher initial level, indicating that the polonium-210 in the grass at the time of collection had already reached between 35 and 80 per cent equilibrium with its parent lead-210.

In Fig. 1 the measured total specific α-activities of the individual dry grass samples (extrapolated to the condition of equilibrium between polonium-210 and lead-210 and hence an approximate measure of the respective lead-210 concentrations) are plotted against the values of mean annual rainfall at the sites of collection. A linear relation is clearly suggested, the value of the correlation coefficient being 0·87. The lead-210 concentrations have also been found to be related to the β- and γ-activities due to fission products[4] for which, as is well known, the predominant mechanism of deposition is wash-out in rainfall. No correlation was found between the total α-activity of the grass and that of the soil.

To account for these observations, two possible mechanisms might be postulated: (*a*) uptake of lead-210, or one of its short-lived precursors from the soil, and (*b*) direct deposition in rain of a partial equilibrium mixture of lead-210, bismuth-210 and polonium-210, produced by decay of atmospheric radon-222. While uptake from the soil probably occurs to some extent, the observed correlation with rainfall and with fission product activity suggests that direct deposition must be important. As shown below, such evidence is supported by the similarity between the observed levels of lead-210 activity in grass and those that might be expected on the basis

(dry weight), and precipitation in this period was 23 per cent of the mean annual value. On the extreme assumption of complete retention of activity by the grass following deposition in rain, values of specific activity could thus have been expected to occur in the range 2·6–26 × 10^{-12} c./gm. of dry grass for each 100 cm. of annual rainfall. It is therefore apparent that, within the rather wide limits of uncertainty inherent in the above assumptions, the levels of lead-210 observed in grass (Fig. 1) are comparable with those that might have been expected as a result of deposition from the atmosphere.

Uptake of Polonium-210 by Sheep

The recognition that polonium-210 occurs as a natural contaminant of grass has suggested the investigation of its possible uptake by herbivores. At the same time that the above grass samples were collected, samples of lamb kidney, stated to be of local origin, were purchased from several shops in each of two Welsh market towns close to areas of high rainfall. Total α-activity was measured on minced, acetone-dried tissue and, in two cases, tissue samples from the cortex and medulla were measured separately. Results of these measurements are given in Table 2.

Table 2. α-ACTIVITY MEASURED IN DRIED LAMB KIDNEY (10^{-12} C. PER GM. WET TISSUE)

1·79	—	—
1·76	1·97	1 10
1 67	2·38	0 66
0 09	—	—
0·12	—	—
0 68	—	—

Alpha spectroscopy[1] was carried out on one sample of whole kidney and the spectrum found to consist of a single line with an energy value corresponding to that of polonium-210. Confirmation that this is the nuclide responsible, and that it occurs in the absence of lead-210, was provided by observations of the decay of total α-activity. The observed localization of activity in the cortex, which is a known characteristic of polonium[6], gives further support to this finding. It is of interest that studies on man, rabbits and rats have shown that between 5 and 15 per cent of the total body burden of polonium may be present in the kidneys[6].

Conclusion

It appears that an important contribution to the observed α-activity of grass may be provided by a process of 'natural fall-out' in which lead-210, resulting from decay of atmospheric radon, together with a fraction of the equilibrium amount of its descendant polonium-210, are deposited by rainfall directly on to foliage. Metabolic uptake of part of this activity by sheep is indicated by the presence in the kidney of polonium-210.

I wish to acknowledge the support and encouragement of Prof. W. V. Mayneord, in whose Department this work was carried out. I am also indebted to Mr. C. L. Day, of the Chester Beatty Institute, who kindly carried out an estimate of the lead content of a sample of grass ash.

PARALLELISM OF CHANGES PRODUCED BY COOLING AND BY DRUGS KNOWN TO AFFECT ADRENERGIC MECHANISMS

By Prof. ELEANOR ZAIMIS

Department of Pharmacology, Royal Free Hospital School of Medicine, London, W.C.1

RESERPINE, guanethidine, bretylium, tyramine, amphetamine, ephedrine and dichloro*iso*prenaline are all substances known either to mimic or to modify adrenergic mechanisms, and their modes of action, still uncertain, have stimulated much work and discussion. During a comparative study of the effects of these drugs on skeletal muscle and on mechanisms mediated either through cholinergic or adrenergic components of the autonomic nervous system, it has been found that the responses obtained from animals at normal temperatures under the influence of these drugs were very similar to those obtained in untreated animals at lowered body-temperatures.

All the experiments have been carried out on cats under chloralose anaesthesia, and when effects of cooling were studied body-temperature was lowered either by the circulation of cold water through a fine rubber bag inserted into the abdominal cavity or by keeping the anaesthetized animal on an unheated operating table. Under anaesthesia, the body- and especially the muscle-temperature of cats tends to fall very rapidly[1]. Both methods produced a rather slow but steady fall in body-temperature without perceptible shivering. Two types of experiments have been performed: in the first the animal was pre-treated for one or several days with the drug under study; in the second, the drug was administered during the actual experiment. The results with tyramine, ephedrine and dichloro*iso*prenaline are from acute experiments only, those with guanethidine, bretylium and amphetamine from both acute and 'pretreated' and those with reserpine from 'pretreated' only.

It is well known that lowered body-temperatures markedly modify physiological processes and alter the effects produced by pharmacologically active substances. For example, induced hypothermia is usually accompanied by a fall in blood pressure and bradycardia. The responses of various drugs are either increased and prolonged or reduced. Throughout the present experiments the following responses have been compared in normal and pretreated animals at various body-temperatures: (1) the effects of adrenaline, noradrenaline, *iso*prenaline and acetylcholine on blood pressure; (2) the contraction of the nictitating membrane elicited by stimulation of the cut peripheral stump of the cervical sympathetic; (3) the effect of vagal stimulation on the heart; for this the left vagus nerve was divided in the neck and the peripheral end, separated from the sympathetic, was excited electrically; (4) the effect of a blocking dose of decamethonium on skeletal muscles.

Cooling

Fig. 1 shows typical results from an untreated animal at various body-temperatures. In this particular experiment the blood pressure of the animal was initially relatively low, and therefore cooling produced a marked bradycardia without further lowering of blood pressure. As cooling proceeds, the onset of the response to adrenaline, noradrenaline, *iso*prenaline and acetylcholine is slowed, the magnitude of the response increases and the duration of action is prolonged. Over the temperature-range examined (39°–26° C.) the magnitude of these responses undergoes a diphasic change: it increases down to about 30° C., but below this temperature starts decreasing. The response to adrenaline is nearly always more affected than that to noradrenaline. On the other hand, the responses of the heart to vagal stimulation and the block produced by decamethonium increase as temperature decreases. Lowered muscle temperature is known to increase, in both animals and man, the magnitude of the effect of depolarizing drugs and markedly prolong their duration of action[2,3]. These changes appear to be independent of the actual metabolic fate of the drug; for example, decamethonium is a substance which is not destroyed in the body, whereas suxamethonium, another depolarizing drug, is rapidly hydrolysed. Cooling, however, prolongs the block produced by decamethonium, more than, or at least as much as, that produced by suxamethonium.

At lowered body-temperature various substances, but especially *iso*prenaline and adrenaline, initiate a phasic variation in the blood-pressure pattern (Fig. 1) possibly due to the initiation of phasic variations in the tone of the peripheral blood vessels.

Reserpine, Guanethidine, Amphetamine, Ephedrine, Bretylium, Tyramine and Dichloro*iso*prenaline

In animals treated either acutely or chronically with any of the above compounds, the effect of vagal stimulation on the heart, the duration of the decamethonium block, and the response of blood pressure to acetylcholine are all increased (Figs. 2–5). The magnitude of these changes is, of course, influenced by the duration of the pretreatment and the dose. The fall in blood pressure produced by *iso*prenaline is also increased in the presence of all these drugs with the exception of dichloro*iso*prenaline, a drug known to antagonize the action of *iso*prenaline[4]. An interesting point is that the effect of dichloro*iso*prenaline on vagal stimulation, acetylcholine and the duration of the decamethonium block appears before *iso*prenaline is antagonized. A phasic variation in the blood pressure pattern appeared regularly again, either spontaneously or initiated by *iso*prenaline, adrenaline and to a lesser degree by noradrenaline. In contrast, the rise in blood pressure produced by adrenaline and noradrenaline ranged from a marked potentiation to more or less complete abolition depending on the drug administered, the dose and the duration of the pretreatment. For example, in acute experiments with tyramine, amphetamine and ephedrine at normal body-temperature, there was an initial reduction of the responses of the blood pressure to both adrenaline and noradrenaline. Throughout this work it was quite obvious that a fall in body-temperature as small as 2–3° C appreciably affected all responses. Great care, therefore, was taken to

DEC 70 μgm.

ensure that the normal body-temperature of the cat, which ranges between 37° and 38° C., was kept constant. Independent of the change produced, however, the effect on adrenaline was nearly always more marked than that on noradrenaline.

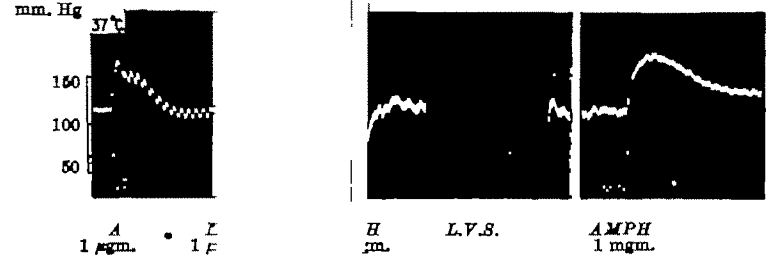
Of the various drugs used, reserpine has produced changes most closely resembling those observed after cooling; the various responses were markedly increased and prolonged even with doses of reserpine which had no apparent effect on the function of adrenergic nerves. The doses used ranged from 5 μgm. to 1 mgm. per kgm. body-weight, and the duration of the pretreatment from one to ten days. Even with a dose as low as 5 μgm. per kgm. administered for five days, the changes produced were quite marked (Fig. 4). In animals treated with reserpine, the administration of small doses of guanethidine, amphetamine or ephedrine further potentiated the various effects.

For the remaining compounds the range of doses used is given in Table 1.

Table 1

	Pretreatment (mgm./kgm.)	Acute (mgm./kgm.)
Guanethidine	0 2–10	1–5
Bretylium	2–20	3–20
Amphetamine	2	0 1–2
Ephedrine		0 3–2
Tyramine		0 1–1
Dichloroisoprenaline		1–4

In the animals pretreated with guanethidine or with bretylium, the potentiating effects appeared long before the blockade of adrenergic neurones. On the other hand, amphetamine and ephedrine were still producing their usual rise in blood pressure in the presence of large doses of guanethidine and bretylium and long after the adrenergic neurones had been blocked (Fig. 2).



A 1 μgm. *I* 1 μ *H* gm. *L.V.S.* *AMPH* 1 mgm.

Fig. 2. Cat, 2·8 kgm pressure responses to vagus pretreated, 8 mgm./kgm. for two days. Blood- oradrenaline (*NOR*), acetylcholine (*ACH*), left *S.*) and amphetamine (*AMPH*)

Discussion

A lowering of body-temperature slows the rate of all physiological processes, but some are more affected than others. For example, for a given fall in temperature the decrease in rate of metabolic and rhythmic processes is two to three times as great as

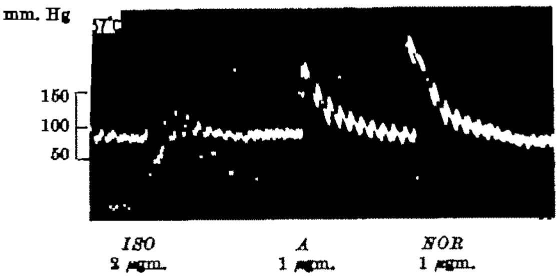


Fig. 3. Cat, 4·6 kgm. Reserpine pretreated, 50 μgm./kgm. for three days. Blood-pressure responses to adrenaline (*A*), noradrenaline (*NOR*) and isoprenaline (*ISO*)

the decrease in rate of diffusion of metabolites[5]. The same is apparently true for the action of various drugs. Some drugs become more effective at lower temperatures, whereas the action of others is reduced. On this basis, Johnson, Eyring and Polissar[6] have classified drugs into two types. Among the first type are those drugs which produce their action by competitively inhibiting enzyme systems. The second type includes a large number of narcotics. There are also drugs exhibiting both types of effect. According to this classification, the drugs used in the present work must belong to the first type, since all become more effective at lower temperatures. Fig. 6 illustrates this point. In two different animals, one at 38° C. and the other at 34° C., the same dose/kgm. of amphetamine was administered. The action produced by the drug was both more pronounced and more prolonged in the cooled animal.

The striking resemblance between the changes produced by cooling alone and those produced by the drugs under consideration, together with the fact that the effects of these drugs are increased at lower temperatures, suggested the possibility of a common basis for their mechanism of action. By far the most obvious change produced either by cooling or by any of the drugs studied is a prolongation of responses elicited by various means; obviously the rate of recovery of the effector cells after activation is slowed. This appears to be independent of either the type of activation (stimulation or inhibition) or the type of nervous control (adrenergic or cholinergic; autonomic or motor). It is therefore very tempting to suggest that the action of these drugs, so far as this phenomenon of prolongation is concerned, is brought about by inhibition of the metabolic processes underlying 'recovery' of a cell after activation.

There is greater uniformity in the changes produced at cholinergic than at adrenergic sites. At cholinergic sites each of the drugs in this group gave rise to the same type of change though to varying extent, whether administered chronically or acutely. On the other hand, at the adrenergic sites there were distinct differences, possibly because by virtue of their chemical structure these substances are presented here with a greater variety of enzymic processes to act upon—processes concerned with the synthesis, storage, release and destruction of the catecholamines all along the adrenergic pathway. The resultant effects, therefore, will depend (*a*) on the direct 'mimicking' ability of the compound (as in the case of tyramine, amphetamine, ephedrine), (*b*) on the ease with which they penetrate cell membranes, and finally (*c*) on their action as inhibitors of various enzymic processes. The wide spectrum of effects which these drugs produce on adrenergic systems could thus be explained.

But what can be the general mechanism by which these drugs interfere with the recovery of a cell after excitation, an effect seen at both cholinergic and adrenergic sites? Possibly by competitively inhibiting enzyme systems concerned with the restoration of a cell after activation. These various molecules look chemically very different, but we cannot really see how they come to be competitive. But take the following

Summary

It has been found that reserpine, guanethidine, bretylium, tyramine, amphetamine, ephedrine and dichloroisoprenaline produce changes closely analogous to those observed in animals the body temperature of which has been lowered. The metabolic basis of these changes is discussed.

This dialysis was followed by a dialysis to a *p*H of 7·22 against the buffer specified as chromatographic developer No. 1 by Allen, Schroeder and Balog[8]. 20–50 mgm. of the mixtures were separated on an '*IRC*-50' column in equilibrium with developer No. 1 at 6° C. The adult hæmoglobin was eluted at this temperature, after which the sickle-cell hæmoglobin was eluted at 28° C. The concentrations of the chromatographic fractions were determined spectrophotometrically at the absorption maxima of carbonmonoxyhæmoglobin at 541 or 415 mμ ; or, in cases where the hæmoglobins were believed to be contaminated with methæmoglobin cyanide, at the isobestic wave-length 522 mμ.

The specific activities of the hæmoglobin samples were measured using a Nuclear-Chicago gas-flow Geiger counter, model *D*-47, equipped with a 'micromil' window. At the high level of specific activities of these hæmoglobins, less than 0·5 mgm. was required per planchette. No corrections for self-absorption were necessary with these amounts of hæmoglobin. A fixed volume of solution, 0·5 or 1·0 ml., was plated.

In experiments with radioactive human sickle-cell hæmoglobin it was necessary to free the material of the fast-moving minor hæmoglobin components in sickle-cell hæmoglobin. This was accomplished by chromatography of 50–100 mgm. of sickle-cell hæmoglobin with developer No. 2 (ref. 8). The major sickle-cell hæmoglobin component was recovered by warming the column to 28° C. The hæmoglobin solutions were concentrated by centrifuging for 18 hr. at 40,000 r.p.m. in the No. 40 rotor of a 'Spinco' preparative ultracentrifuge at 5° C. Concentrated solutions, usually containing 8–15 per cent hæmoglobin, were withdrawn from the bottom of the centrifuge tubes with a hypodermic syringe fitted with a 4-in. 22-gauge needle.

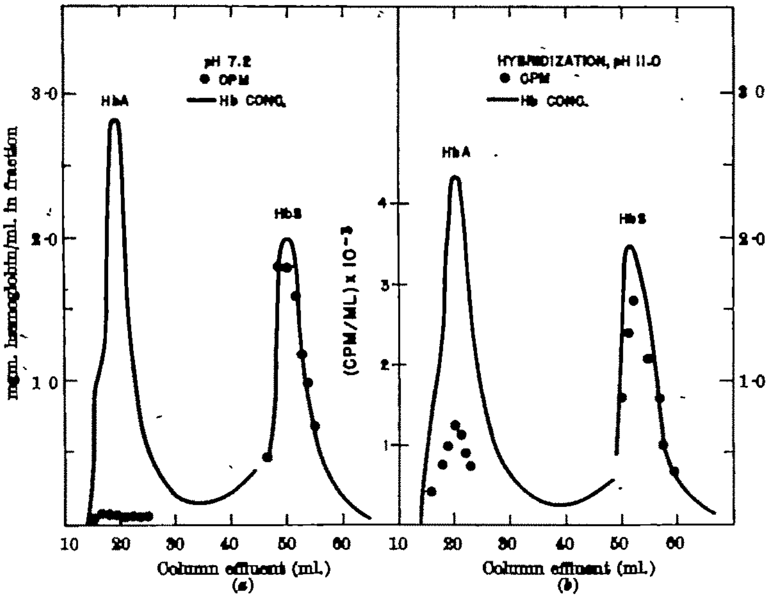

Fig. 1. Transfer of radioactive α sub-units in a mixture of human adult hæmoglobin and carbon-14-L-leucine labelled sickle-cell hæmoglobin dialysed to pH 11 and afterwards dialysed to pH 7·2. (*a*) Experiment 6, (*b*) experiment 4, Table 1.

Preparation of Radioactive Hæmoglobins

The unlabelled hæmoglobins were prepared from freshly drawn blood samples from either normal or sickle-cell anæmic individuals by the procedure of Drabkin[9]. The hæmoglobin was not crystallized[9].

It was desired that the radioactive hæmoglobins used in the hybridization experiments be uniformly labelled in the α and the β chains. L-leucine was chosen because of the abundance of this amino-acid in the molecule and the presence of leucine in both α and β N-terminal peptides. It has recently been shown that there are close to an equal number of leucine residues in both chains[10]. Uniform labelling, therefore, should lead to equal specific activities in the α and β chains.

The radioactive hæmoglobins were prepared from the red blood cells of anæmic donors. Blood samples containing 15–40 per cent reticulocytes were used within 2 hr. after the blood was drawn. Following four washings with cold isotonic saline solution, the red cell suspensions were incubated by a modification of the procedure devised for rabbit reticulocytes by Borsook *et al.*[11].

The complete incubation mixture was prepared using the following stock solutions:

(*a*) 0·13 *M* sodium chloride, 0·005 *M* potassium chloride, 0·0075 *M* magnesium chloride, in redistilled water.
(*b*) 0·22 *M* glucose in solution (*a*), prepared fresh for each incubation.
(*c*) 0·01 *M* ferrous ammonium sulphate in solution (*a*), prepared fresh.
(*d*) 0·27 *M* sodium bicarbonate in redistilled water, prepared fresh.
(*e*) 0·01 *M* glutamine in solution (*a*), stored frozen.
(*f*) Amino-acid mixture: *l*-alanine 180, *l*-arginine 100, *l*-aspartic acid 330, *l*-cysteine 50, glycine 400, *l*-histidine hydrochloride 500, *l*-isoleucine 52 (*l*-leucine 52), *l*-lysine hydrochloride 330, *l*-methionine 50, *l*-phenyl alanine 260, *l*-proline 160, *l*-serine 175, *l*-threonine 200, *l*-tryptophan 60, *l*-tyrosine 150, *l*-valine 370, *l*-hydroxyproline 150 (amounts of amino-acids expressed as mgm. per 1,000 ml. of solution *a*). After boiling to dissolve all amino-acids, the pH was adjusted to 7·0 with 5 *N* sodium hydroxide. This stock solution was stored frozen in small lots which were thawed out as needed.

The following amounts of the above solutions were added, in the order given, to 10 ml. of packed red blood cells: 5·85 ml. of amino-acid mixture, 0·60 ml. glucose solution, 1·2 ml. glutamine solution, 1·8 ml. of sodium bicarbonate solution, 11·7 ml. ferrous ammonium sulphate solution. Seven micromoles, 50 µc., of Nuclear-Chicago uniformly labelled radioactive L-leucine, dissolved in 0·5 ml. solution *a*, was then added to the mixture. In these incubations the cold L-leucine was omitted.

The cells were incubated for 4 hr., washed four times and lysed with distilled water and toluene. After removal of cell debris by low- and high-speed centrifugation, the resulting hæmoglobin solutions were dialysed against several changes of distilled water to remove unincorporated carbon-14 labelled L-leucine. The specific activities of the hæmoglobins in several preparations were between 3,000 and 7,000 c.p.m./mgm.

Results of Hybridization Experiments

The results of a typical hybridization experiment and the chromatographic separation of the two hæmoglobins are shown in Fig. 1*b*. In Fig. 1*a* the results of a chromatographic separation of the same materials mixed at pH 7, but not dissociated at pH 11, show that there is little contamination of human adult normal hæmoglobin by the radioactive sickle-cell hæmoglobin. Inspection of the curves in Fig. 1 shows that no new chromatographic species have appeared as a result of the dissociation of the mixture at pH 11 and that transfer of activity from the sickle-cell hæmoglobin to the adult hæmoglobin occurs. The specific activity of the adult hæmoglobin after dissociation and recombination is approximately one-third that remaining in the sickle hæmoglobin. In Table 1, experiments 1–9 summarize the results of several similar experiments in which the hæmoglobins were dissociated in acid and alkaline solutions. The specific activities given in Table 1, together with standard deviations, are average values of the specific activities of all chromatographic fractions containing more than 0·2 mgm./ml. of hæmoglobin. This usually accounted for more than 80 per cent of the recovered

Significance of Hæmoglobin Hybrid Formation

The hybrids labelled with carbon-14 described here are useful materials in two general areas of hæmoglobin studies. First, any peptide fragment isolated from digests of the whole molecule may be identified with respect to the sub-unit of origin. An example of this was the first identification of the aberrant or non-transferring sub-unit in the normal hæmoglobin/sickle-cell hæmoglobin system with the β *N*-terminal peptide[2]. In the second kind of study, a sub-unit transferring between two hæmoglobins may be readily followed as in the case of reactions between hæmoglobins A and F (ref. 12), S and H (ref. 13), and more recently in interspecies systems between adult hæmoglobin and rabbit hæmoglobin. In the latter case, through the use of $\alpha_2^*\beta_2$, the compositions of the two interspecies hybrids were readily recognized (unpublished work from this Laboratory).

This investigation was supported in part by a grant (*H*-3394) from the National Institutes of Health, United States Public Health Service. We wish to thank Drs. R. T. Jones and W. A. Schroeder for their advice in connexion with the chromatographic procedures, also Dr. P. A. Sturgeon, Children's Hospital, Los Angeles, for supplying us with the blood samples and the hæmotological data.

solutions of formic
erved that the yields
on products from the

solute dropped sharply on going from acid to neutral conditions. Somewhat similar pH effects have since been noted in various other aqueous systems[2]. As yet, however, no satisfactory explanation has been offered for these results.

In the course of an investigation of the effect of cobalt-60 γ-rays on aqueous solutions of various simple

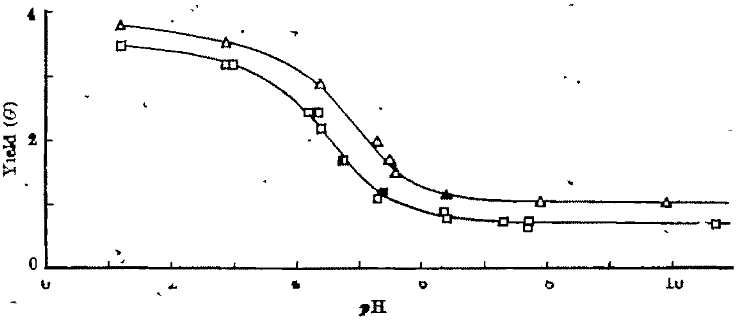

Fig. 1. Dependence on *p*H of the yields of acetone and hydrogen from aqueous solutions of *iso*propanol (10^{-3} *M*) irradiated with cobalt-60 γ-rays *in vacuo*. □, acetone; △, hydrogen

aliphatic alcohols, carried out in this laboratory, particular attention has been directed to the study of *p*H effects *in vacuo*.

In this communication we present some results obtained from *iso*propanol solutions. The main product was found to be acetone. The yields of acetone and of hydrogen from *iso*propanol solutions (10^{-3} *M*) were studied as a function of *p*H over the range *p*H ~ 1 to ~ 10. In the more strongly acid solutions (*p*H < 3) and in solutions at *p*H > 7, the yields were linear with dose, up to the highest doses used (4×10^{18} eV./ml.). In the range *p*H ~ 3 to ~ 6, however, the yield–dose plots were non-linear, falling off with increasing dose. Detailed examination down to the lowest practical doses showed that initially there was a high yield, but this could not be accurately determined. Above about 3×10^{17} eV./ml., the deviation of the plots from non-linearity was not quite so pronounced. *G*-values (molecules/100 eV.) for the yields of hydrogen and acetone in this particular *p*H range were, therefore, computed from results obtained using doses ranging from 3×10^{17} to $1{\cdot}2 \times 10^{18}$ eV./ml. Fig. 1 shows the *p*H-dependence of the radiation-yields obtained in this manner.

It was apparent from these results that some back reactions were taking place in solutions irradiated at *p*H > 3. Experiments were therefore carried out in which acetone was added to *iso*propanol solutions (10^{-3} *M*) prior to irradiation. Some results are shown in Table 1. In the *p*H range 3–6, such additions lead to notable decreases in the yields of hydrogen. It would appear, therefore, that the *p*H-dependence in *iso*propanol solutions is largely associated with back reactions involving the acetone produced by radiation. Essentially similar results have been observed with solutions of methanol (Lyons, Scholes and Smith, unpublished results) and of ethanol (Nixon and Scholes, unpublished results), where it has been found that the corresponding aldehydes enter into the back reactions.

Chemical reactions induced by ionizing radiations in dilute aqueous systems are due to the free radicals, denoted as H and OH, produced by the action of the radiation on the water[3]. In addition, there is some primary formation of 'molecular' hydrogen and hydrogen peroxide[4]. The overall radiolysis of water is conventionally represented as:

$$H_2O \rightsquigarrow H, OH, H_2, H_2O_2 \qquad (1)$$

Radical formation is the result of the excitation and ionization processes which occur as a consequence of the absorption of the ionizing radiations[5]. There is some controversy, however, about the fate of the electrons formed from the ionization process. Lea and Gray[6], Weiss[6] and Platzmann[7] have considered that the ejected electron is captured by a water molecule at some distance from the parent positive ion and exists, possibly attached to a water molecule, until interaction with the aqueous medium allows formation of a hydrogen atom according to the process:

$$H_2O^- \rightarrow H + OH^- \qquad (2)$$

Weiss[8] has discussed questions regarding the stability of the positive and negative ions from water, pointing out that they may have a life-time long enough to enable them to undergo chemical reactions with the solute present. Deaerated solutions of monochloroacetic acid were found to be systems in which the results could best be explained in terms of reactions of the negative ion, H_2O^- (the electron in water or 'polaron')[9].

The results reported above can only be explained if we assume the presence in irradiated neutral and alkaline solutions of *iso*propanol of two forms of the 'hydrogen atom' (cf. ref. 10). One of these dehydrogenates *iso*propanol, but the other cannot and reacts with acetone and probably also to some extent with the hydrogen peroxide produced according to reaction (1). Since it seems highly unlikely that H_2^+ and H could be the two forms under these conditions of *p*H, we must conclude that the species are H and the electron (polaron). Furthermore, they are both produced in the act of radiolysis, and the results indicate that, under these conditions, $G_{\mathrm{H}} = 0{\cdot}6$ and $G_{\mathrm{H_2O^-}} = 2{\cdot}3$. These hydrogen atoms could very well arise from excitation processes of the type[6]:

$$H_2O^* \rightarrow H + OH \qquad (3)$$

The effects of *p*H which, as described above, are essentially due to a back reaction involving acetone could then be ascribed to the competition:

$$H_2O^- + H_2O^- \rightarrow 2H_2O + H \qquad (4)$$

$$H_2O^- + CH_3.CO.CH_3 \rightarrow H_2O + [CH_3.CO.CH_3]^- \qquad (5)$$

In the *p*H range 3–6, addition of acetone depresses the yield of hydrogen by influencing the competition in favour of reaction (5), and for the same reason one would expect non-linearity of the yield–dose plots. From the experiments in the presence of acetone the ratio of the rate constants of reactions (4) and (5) can be calculated as $k_4/k_5 = 2{\cdot}3$. It should be pointed out that H_2^+, which is formed in acid solutions[11], could still be a reacting species at low *p*H.

mum hydrogen yield
irradiation of mono-

chloroacetic acid solutions at pH 1·20 (ref. 9). We have confirmed that there is a maximum in acetone solutions ; at pH 1·2 this occurs at a concentration of 10^{-2} molar. These are examples where the solute itself can react both with the hydrogen atom (or H_2^+ in acid solution) and with the polaron. At low concentrations of solute in acid media, reaction (4) is predominant and dehydrogenation processes occur. As the concentration is increased, however, increased scavenging is offset by reactions of the polaron with the solute, for example, reactions (6) and (7). Hence, the hydrogen yield goes through a maximum.

In a study of the exchange reactions induced by radiation in D_2–H_2O, Gordon and Hart[13] observed that above pH ~ 7 the yields of HD fell off very rapidly, and this was attributed to ionization of the OH radical. However, these particular results could be accounted for by the decrease in the extent of reaction (4) in this pH region. Above pH ~ 8 these authors noted a significant increase in the yields of hydrogen gas, an observation which would suggest that the life-time of the polaron can be sufficiently long to allow recombination to form molecular hydrogen. Such considerations, together with the large ratio of (G_{H_2O}) (G_H), would tend to support the suggestion[8] that the polarons contribute towards the molecular hydrogen yield.

We thank Prof. J. Weiss for valuable discussions and for his encouragement of this work.

ted during the cruise
lay until July 1958[3].

The first core described, 3738, was taken on the lower slopes of a group of abyssal hills on the western edge of the Iberian abyssal plain[4] (Station 3738, 41° 00′ N., 15° 08′ W., corrected depth 5,267 m.). The second core, 3780, was taken at the bottom of a bank about 3 m. above the abyssal plain (Station 3780, 41° 26′ N., 14° 43′ W., corrected depth 5,333 m.). They were obtained with a piston corer, and were not oriented with respect to the direction of the Earth's present magnetic field. The core 3738 is about 4 m. long ; results on only the top 3 m. are presented here. Core 3780 is 6 m. long.

Core 3738 consists of brown clay and foraminiferal ooze, and of mixtures of these two types of sediment ; evidence of burrowing occurs at intervals throughout the length of the core. A summary of the lithology

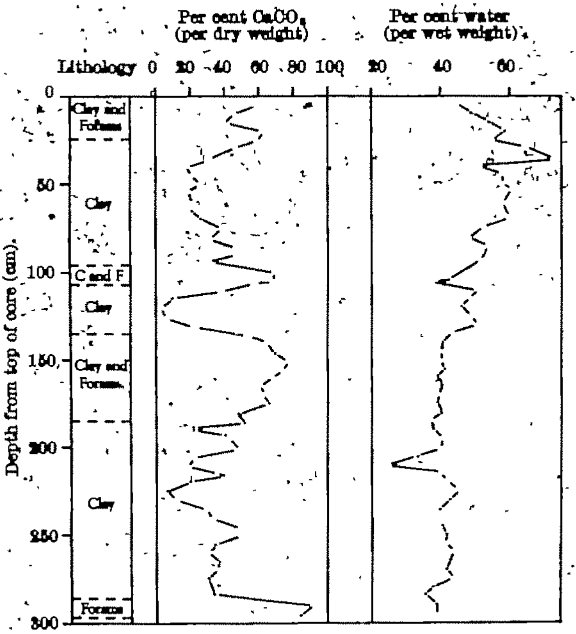

Fig. 1. Core 3738: lithology, percentage CO₂—(calculated as calcium carbonate) and percentage water plotted against depth of the core

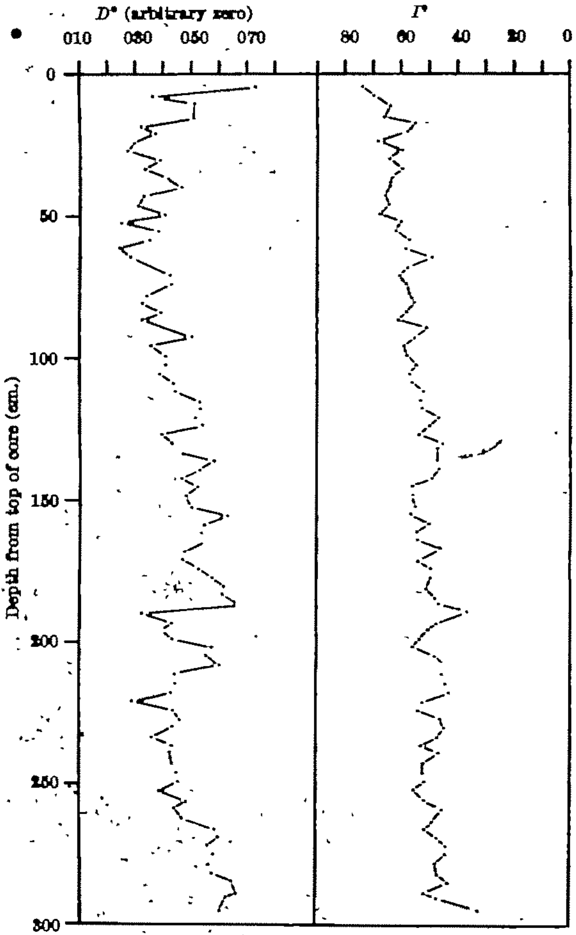

Fig. 2. Core 3738: values of $D°$ and $I°$ plotted against depth of core

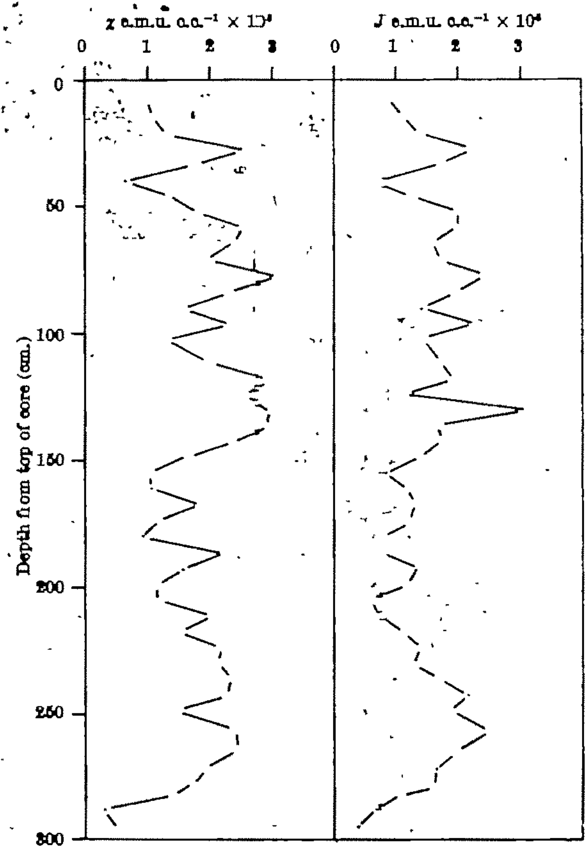

Fig. 3. Core 3738: values of χ and J plotted against depth of core

is given in Fig. 1, with the percentage of total carbonates and the water content. The carbonate content is given as a percentage of the dry weight and the water content as a percentage of the wet weight. The samples taken for the investigation of the remanent magnetization were in the form of cylinders 2·7 cm. in length and in diameter, and were taken immediately after the core had been opened and before it had dried out significantly; sampling was continuous down the core. All the samples were oriented in the same way relative to the core as a whole; the direction of the length of the core can be expected to be the vertical. The direction and intensity of the remanent magnetization of each sample was measured on an astatic magnetometer similar to that described by Collinson *et al.*[5]. The susceptibility was measured with an a.c. bridge by comparing the samples with standards.

The magnetic data are shown in Figs. 2, 3 and 4. Fig. 2 shows the variation in the values of declination, D (azimuth), and the inclination, I (dip), down the core. The values of D are plotted with an arbitrary zero and the values of I with the direction of increased depth down the length of the core as 90°. The present value of I in the area from which the core was taken is about 58° (ref. 6). Fig. 3 shows the variation in intensity of remanent magnetization, J, and the variation in magnetic susceptibility, χ, down the core: the values are given in e.m.u. c.c.$^{-1}$ of wet sediment. Fig. 4 shows histograms of the values of D and I of all the specimens measured.

The minerals which cause the magnetization have been investigated only by thermo-magnetic analysis and two sets of experiments were carried out. In

in the type of core described above, and this can be seen in the histograms (Fig. 5).

The cores have been stored horizontally since collection before being measured and in some cases for as long as eighteen months ; there are no results which suggest instability over this length of time. Stability is also suggested by the correspondence between changes in inclination and compaction.

The results suggest that the magnetization of the sediments of the type found in core 3738 is due to the Earth's magnetic field during deposition or soon after deposition while the core is still wet and is being reworked by burrowing animals. Studies are being made of longer cores and of cores taken within 200 m. of each other to see whether reversals of polarity of the sediments occur and whether correlation can be found between adjacent cores.

I should like to thank members of the Department of Geodesy and Geophysics and the National Institute of Oceanography for their help and advice and the Royal-Dutch Shell Group for a scholarship.

ASTROPHYSICS

Gravitational Red Shift of Hydrogen 21-cm. Radiation as a Method to measure Galactic Gravitational Potential

THE 21-cm. hyperfine emission from the neutral hydrogen atom has an exceedingly narrow natural width, corresponding to a transition probability of $2 \cdot 84 \times 10^{-15}$ sec.$^{-1}$. Consequently, in principle, small variations in its frequency resulting from gravitational effects offer a method to measure gravitational potential in our Galaxy, provided that they are not too small compared with the temperature broadening. The galactic disk is well known to emit 21-cm. radiation, and from its observed Doppler shifts the radial dependence of its rotational velocity has been deduced. Because the true Doppler shifts of galactic rotational motion are large, it may be difficult to detect the expected gravitational shift, which also looks like a Doppler shift. But, in principle, the two effects may be separated because the true Doppler shifts have opposite signs at the same radius on opposite sides of the galactic centre, whereas the gravitational frequency shift has the same sign.

Added to the true Doppler shift, and the gravitational frequency shift, there is the temperature broadening of the 21-cm. line. For radiation emitted near the centre of the galaxy ($R \leq 1$ kpc) which propagates out to the Earth ($R = 8 \cdot 2$ kpc) the true Doppler shift has an average value of about 25 km./sec., and the temperature broadening is about 1·0 km./sec. corresponding to a temperature of 150° K. for neutral hydrogen.

Assuming the numerical values[1] at present accepted for the galactic gravitational potential, we compute the gravitational frequency shift for this radiation to be $\sim 0 \cdot 7$ km./sec. Using the usual gravitational shift formula[2]:

$$\frac{\Delta \nu}{\nu} = \frac{\varphi_2 - \varphi_1}{c^2}$$

where φ_2 and φ_1 are the potentials at the point of emission and absorption respectively.

This frequency shift is equivalent to a Doppler shift resulting from a relative velocity v:

$$\frac{\Delta \nu}{\nu} = \frac{v}{c}$$

Consequently, the apparent Doppler shift velocity equivalent to the gravitational frequency shift is given by:

$$v \simeq \frac{1}{c}(\varphi_2 - \varphi_1)$$

and is positive (shift to bluer frequency) or negative (shift to redder frequency) accordingly as the photon comes to the Earth from a region of higher or lower gravitational potential. From the hypothesis that the galactic gravitational potential increases with increasing radius it follows that photons coming to us from near the centre of the Galaxy are red shifted whereas those coming from radii larger than 8·3 kpc are blue shifted.

Now let the potentials[1] be taken as $|\varphi_1| = 2 \cdot 9 \times 10^{15} \frac{\text{cm.}^2}{\text{sec.}^2}$ at $R_1 = 0$ kpc and $|\varphi_2| = 0 \cdot 82 \times 10^{15} \frac{\text{cm.}^2}{\text{sec.}^2}$ at $R_2 = 8 \cdot 2$ kpc, where we have multiplied by a factor (Schmidt, Martin, private communication) of 2 to account for a revised value of the total galactic mass. Then the equivalent velocity is:

$$|v| = \frac{1}{3} \times 10^{-10}[2 \cdot 9 - 0 \cdot 82] \times 10^{15} \frac{\text{cm.}}{\text{sec.}} = 0 \cdot 7 \text{ km./sec.}$$

If the galactic mass or galactic diameter should be different from the presently accepted values (ref. 1 and Schmidt, Martin, private communication) the equivalent velocity measured would differ from the value computed here.

A determination of the equivalent velocity for some region of the Galaxy measures the difference in gravitational potential between the point of emission and the Earth, and so gives independent information on the mass of the Galaxy. However, the effect is small, and will require to be detected against a background of large rotational Doppler shifts. In principle, this may be done in the following way, assuming the matter of the disk to be distributed symmetrically with respect to the galactic centre. Suppose one integrates all observed Doppler shifts, weighted by observed relative intensity, over an angular interval symmetric with respect to the galactic centre, $\vartheta \leq \theta \leq -\vartheta$, where θ is the angle between the direction of observation and the direction of the galactic centre. Then the sum of terms coming from all true Doppler shifts should add to zero, because these are positive and negative accordingly as θ is positive and negative, whereas the terms arising from gravitational shifts have always the same sign, and consequently add. The resultant sum when divided by the integral of total amount of neutral hydrogen present in that region is equal to the average gravitational shift in that region. If the effect is too small to measure one may nevertheless be able to determine an upper limit for the galactic mass.

There are, of course, various other effects which can distort the above simple approach and which may have to be taken into account such as the motion of the Sun, and possible errors in the determination of the Galactic centre.

The first might be treated in the following way. Assume the distribution of mass as symmetrical with respect to the line between Earth and galactic centre. Let the integral I over the given angular interval 2ϑ, symmetrical with respect to the galactic centre, be plotted versus ϑ for various heights of observation above, in and below the galactic plane, both in the direction of the galactic centre and in the opposite direction. In principle, these sets of data are sufficient to allow determination of the velocity of the solar system in the galactic plane with respect to the galactic centre, because resulting linear effects change sign for the two sets of data.

If the centre of the galaxy x_0 has been incorrectly identified, its effect may be minimized as follows. Compute $I(2\vartheta)$ for various assumed positions of the centre, on both sides of x_0; then integrate $I(2\vartheta)$ over x. The resultant depends on the gravitational red shift, and the error caused by wrong choice of

centre is ~(Δλ x measures the region of

Table 1. Resulting Intensity of Magnetic Fields on March 29 (Spectra taken at 7 hr. 53 min and 56 min.) and on August 18 (Spectra taken at 10 hr. 34 min., 39 min. and 41 min.)

Line	Method	Splitting	Intensity $g = 4/3$ gauss	Intensity $g = 1$ gauss
March 29				
D_1	tracing	0·110 Å.	2,500	3,400
D_1	visual	0 117 Å.	2,700	3,600
August 18				
D_1	tracing	0·121 Å.	2,800	3,700
D_1	visual	0·134 Å.	3,100	4,100
λ3706	visual	0 054 Å.	3,200	4,200

effect of this type has been found for flares outside the spots.

The flares considered are: the first one on March 29, 1959, 7h. 46m.–9h. 30m., maximum phase at 7h. 43m., importance 2, position 17 N., 36 E., maximum H_α line width 4·0 Å., maximum H_α central intensity ~ 125 per cent of the continuum[2]. Its part was projected on a spot, the maximum magnetic intensity of which was ascertained to 2,500 gauss on March 30, and 2,400 gauss on March 31 (ref. 3). No magnetic measurement was at our disposal on the day of the flare appearance. The second flare was observed on August 18, 1959, 10h. 13m.–12h. 35m., maximum phase between 10h. 25m. and 10h. 31m., importance 3, position 12 N., 32 W., maximum H_α line-width $\gtrsim$ 5·6 Å. Measured maximum magnetic intensity of the spot associated was ascertained to 2,500 gauss on the day of the flare appearance and 3,100 gauss on August 19 (ref. 3). Spectra of both the flares were photographed by Miss Růžičková.

Fig. 1 presents profiles of the sodium D_1 and D_2 lines in the spectrum of the flare of August 18, traced by a Khol recording microphotometer. The linear dispersion was 1 Å./mm. and the resolving power 10^5. In the ultra-violet region the dispersion was 0·67 Å./mm.

The splitting was measured by two methods: from the tracings recorded, and visually from a projection of the negatives enlarged twenty times. The resulting values are given in the third column of Table 1. The splitting of the Ca II line was too small to be distinguished by a microphotometer tracing.

Due to the fact that the σ and π components are not separated, the determination of the magnetic intensity is rather uncertain. As both the flares appeared not far from the centre of the solar disk and directly over sunspots, the path of the radiation can be assumed as parallel with the magnetic lines of force. In such a case we may consider the σ components only, and we obtain the values of intensity given in the fourth column of Table 1. As, however, metallic emission lines of flares seem to be formed rather high in the chromosphere[4], we cannot be sure about the course of lines of force in the emitting area and weaker π components can also be present. Therefore, we add as the upper limit the case of $g = 1$ in the last column of Table 1.

Although the precision of our measurements, made without any polarization equipment, is not very high, one can be sure that during these flares strong magnetic fields—approximately of the same order as in the photospheric part of the sunspots—existed rather high in the chromosphere. This supports former conclusions[5] that the gradient of the magnetic intensity above sunspots is extremely low. As always, the most intensive regions of flares were photographed by the Ondřejov spectrograph; our result also shows that even very bright parts of chromospheric flares can exist directly in those parts of the solar atmosphere where very strong magnetic fields are present.

GEOPHYSICS

Stress-Dependent Magnetization in Some Quartz-Dolerites

WHEN non-axially magnetized cylindrical specimens of a quartz-dolerite have been axially compressed in an axial magnetic field of the order of the Earth's, their natural remanent magnetism vectors have changed towards the ambient field direction.

The empirical functions:

$$K = \frac{P_\varphi - P_{\varphi 0}}{\tan 90 - \varphi} \pm 7 \text{ per cent} \qquad (1)$$

and:

$$I_T = \frac{I_A}{\tan 90 - \varphi} \pm 10 \text{ per cent} \qquad (2)$$

fit the measured changes where P_φ is the pressure applied to produce a vector making an angle φ with the field and compression direction, K is a parameter dependent upon the magnetic minerals and the ambient field-strength, and I_A and I_T are the axial and transverse components of the natural remanent magnetism intensity.

An example for specimen number 18*H* is given in Table 1.

Table 1

P_φ (kgm./cm.^{2})	$90 - \varphi$ (°)	Tan $90 - \varphi$	I_A (arbitrary	I_T units)	Field oersteds
0·0	−59	−1·68	−17·0	10·0	1·8
127·2	−49	−1·15	−13·8	12·0	1·8
254·2	−31	−0·61	− 6·1	10·0	1·8
381·6	−14	−0·25	− 2·9	11·5	1·8
508·8	+21	+0·38	+ 4·2	10·8	1·8
636·0	+55	+1·43	+13·0	9·0	1·8

Putting $\tan 90 - \varphi = y$, $P_\varphi = x$ and $K = 1/b$, then the least squares solution for the straight line $y = bx + c$ leads to:

$$K_{1 \cdot 8} = 217 \pm 13$$

similarly:

$$I_T = 10 \cdot 5 \pm 1 \cdot 0$$

The error in K is equivalent to an error of 4°–5° in φ, about twice the repeatability of a measurement, a difference attributed to magnetic inhomogeneities accentuated by the stress treatment. Results for several specimens from the same dyke locality in fields up to 2·4 oersteds and pressures up to 636 kgm./cm.^{2} (that is, 30–50 per cent of that to produce fracture) are given in Table 2.

Stereograms of natural remanent magnetism vectors for a number of cores from specimens 15 and 18 (Fig. 1) are examples of an unstable and a stable type respectively. Their K-parameters are a measure of their stabilities under conditions of geological significance. Specimen 18 has retained its magnetization in the original Permian thermal remanent magnetism direction[1]. The present field makes angles, measured almost in the meridian, of 90° and 115° with the natural remanent magnetism of specimen 18*H* and the Permian field respectively. This indicates the maximum geological compression (P_{90}) on the core in the present field direction since:

Table 2

Specimen	Core	Field	K
15	*H*	0·6	295 ± 20
15	*C*	1·2	98 ± 3
15	*C*	1·8	55 ± 5
15	*G*	2·4	63 ± 6
18	*H*	0·6	590 ± 90
18	*H*	1·2	270 ± 10
18	*H*	1·8	217 ± 13
18	*B*	1·2	590 ± 25
18	*B*	2·4	344 ± 11
20	*I*	0·6	575 ± 30
21	*B*	1·8	147 ± 15

$$P_{115} - P_{90} = 600 \tan (90\text{–}115)$$

so

$$P_{90} = 300 \text{ kgm. cm.}^2\text{, where } P_{115} = 0$$

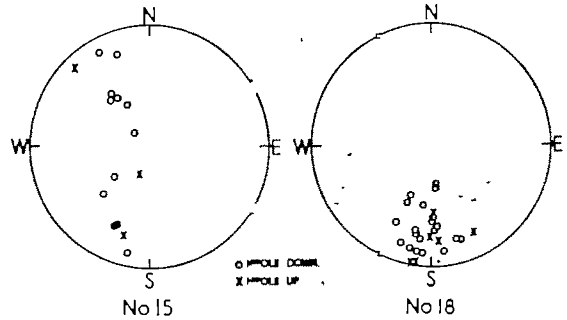

Fig. 1

An experiment on one specimen shows that the K_{TRM} is three or four times greater than its K_{NRM} in the Earth's field. This suggests that the stress dependence is due to unmixing of higher temperature magnetic phases[2]. One specimen showed a decrease of K_{NRM} after repeated stress treatment. It is hoped to continue these measurements over a wider range of field and stress and rock-types and to examine the magnetic minerals optically.

antiferromagnetic order give rise to a ferromagneti
moment. An explanation of this type has been pu
forward for the weak ferromagnetism of α Fe_2O
(ref. 3). More direct evidence of antiferromagnetism
is being sought by neutron diffraction. The electrica
resistance of the pseudo-palladium alloy shows n
marked anomaly in the temperature-range concerned
but a negative magneto-resistance is found in lo
fields at 4·2° K.

The co-existence of ferromagnetism and anti
ferromagnetism might lead one to expect exchang
anisotropy effects like those in the Co–CoO system
(ref. 4), or in the perhaps more analogous disordere
Ni_3Mn alloy (ref. 5), but we have not found the
palladium alloy to be appreciably affected by coolin
in a magnetic field.

In an alloy containing 5 per cent each of rhodium
and silver, the dependence of the susceptibility o
the field appears at lower temperatures, but is wel
established at 4·2° K.; although the susceptibilit
of a binary alloy of palladium with 5 per cent rhodium
which has a very enhanced susceptibility at 20° K

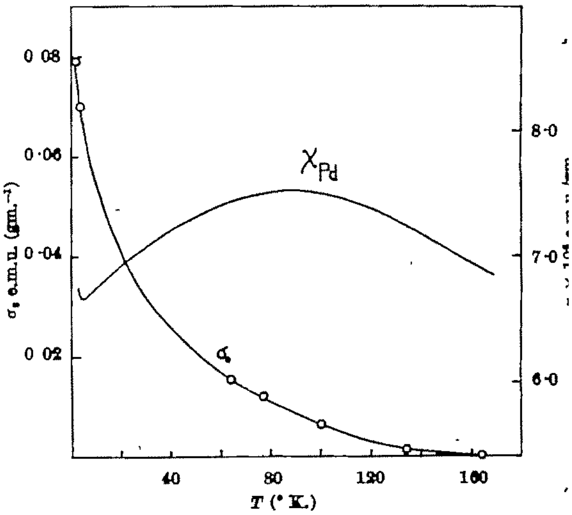

Fig. 2. Spontaneous magnetization (σ_s) against temperature for a palladium 1 per cent silver 1 per cent rhodium alloy and magnetic susceptibility (χ_{Pd}) of pure palladium

(ref. 6), has been found by us to show only an extremely small dependence upon field at helium temperatures. This would suggest that rhodium alone depresses the susceptibility maximum of pure palladium, thereby raising the low-temperature susceptibility but preventing the appearance of local ferromagnetism. A palladium 1·6 per cent silver alloy also shows no anomalous behaviour at 4·2°.

This investigation is being extended to related alloys, and a fuller account will be published elsewhere. We thank the Mond Nickel Co. (Precious Metals Division) for the provision of the alloys, the Royal Society and the Atomic Energy Research Establishment, Harwell, for financial support, and Mr. R. V. Bellau for assistance with the electrical measurements.

Direct Observation of Surface Contamination formed in Demountable Vacuum Systems

The visible contamination of specimens examined in the electron microscope is the result of a reaction between the electron beam and matter adsorbed on the irradiated surface. This adsorbed material is known to consist of hydrocarbon molecules[1], though it may also contain some water molecules; it exists on surfaces in all demountable vacuum systems. The layer is troublesome in many experiments and processes involving such systems, but evidence of its presence is only indirect and little is known about its thickness or composition. It is particularly noticeable in high-resolution shadow-casting for the electron microscope (unpublished work), since it limits the resolution by causing a fine background structure. In the course of an investigation of this structure, a method was found for studying the adsorbed layer directly, and also for estimating its thickness. It was found that the layer was visible in the electron microscope when viewed end-on and sandwiched between two carbon films (see Fig. 1). The procedure is carried out as follows.

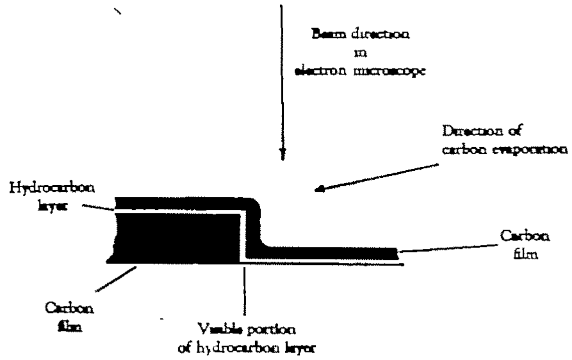

Fig. 1. Diagram showing the manner in which a contaminant layer, deposited from a vacuum system, can be viewed directly in the electron microscope

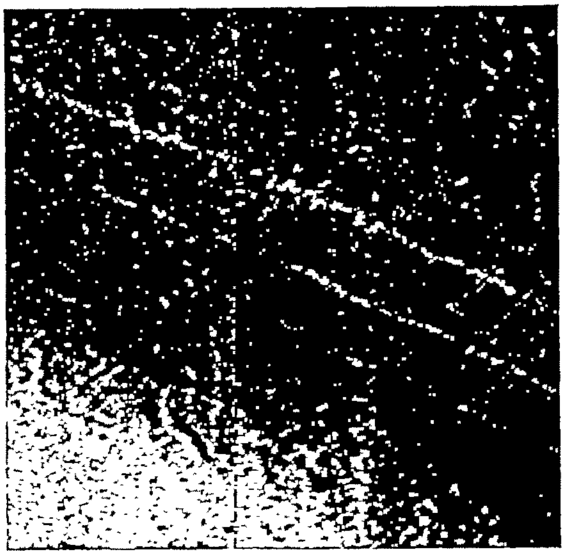

Fig. 2. A contaminant layer deposited from a vacuum system viewed end-on in the electron microscope; each white line represents a different layer (see text). (× 400,000)

A carbon film about 300 Å. thick is deposited on a glass slide and floated on to a water surface. A second carbon film about 100 Å. thick is deposited on a freshly cleaved mica surface. A drop of water is placed on the coated mica, and a few small pieces of the floating carbon film transferred to the drop with a very fine glass rod. The excess water is removed with filter paper and the thick carbon film allowed to dry on to the thinner The second film provides vertical steps A further carbon film is now evaporated against one of the steps at an angle of 26½° to the horizontal as shown in Fig. 1, the direction of deposition being perpendicular to the line of the step. The combined films are floated on to water, and the portion containing the step mounted on a grid. The step edge is located in the electron microscope, and a thin line transparent to electrons and separating the final carbon deposit from the step face can be clearly seen. If the orientation of the specimen is such that the direction of the incident electron beam is not parallel to the step face, then the line disappears, as might be expected.

A simple experiment shows that the thickness of this line depends upon the time for which the step face is exposed to the atmosphere in the pumping plant. This is carried out by depositing several secondary carbon layers, in a series of short bursts spaced by varying intervals of time. In this way the change in thickness can be studied in a single electron micrograph, such as that shown in Fig. 2. Here, the material in the line marked *A* was deposited while the plant was pumped down from atmospheric pressure and then evacuated with the diffusion pump for 30 min. The line *B*, only just visible, was formed in an interval of 1 sec. between two depositions of carbon, the line *C* was formed in 20 min. and *D* in 10 min. During these intervals, the system (pumped by a 'Metrovac' 03*B* diffusion pump, with no cold trap, using 'Apiezon *B*' oil was at a pressure of about 10^{-4} mm. mercury. It can be seen from the electron micrograph that the width of the line depends on the time of exposure to the atmosphere in the system. This indicates that the line transparent to electrons represents an end-on view of a layer of material

Rare Modes in the Spontaneous Fission of Californium-252

CALIFORNIUM-252, a man-made trans-uranic element, having an α-particle half-life of 2·2 yr., undergoes spontaneous fission. Approximately one fission occurs per 38 α-particles, and the material is therefore well suited to an investigation of the possibility of rare modes of spontaneous fission.

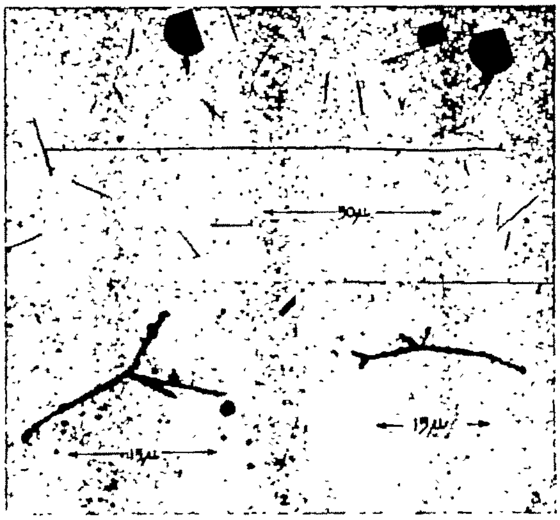
In slow-neutron fission[1,2], fast-neutron fission[3] and photofission[4,5], two rare fission modes have been established. In one the emitted particle is long-range and uniquely an α-particle; in the other, short-range particles, apparently light elements, appear to be emitted in the process. There is also, in slow-neutron fission, some evidence for fission into three particles of approximately equal mass and kinetic energy, but this is not unambiguous[6].

Observation of the quaternary fission of uranium-235 was claimed in 1946 by a French group[7], but later work in this laboratory[8] showed that, if it occurred, the frequency was much less than that estimated from the French investigation.

In the present experiment, where minute traces of californium-252 were incorporated into Ilford K_5 and E_1 emulsions, the conditions of observation were more favourable than in any of the earlier nuclear emulsion studies. Since the plates required no irradiation, they contained only the californium-252 fission and α-tracks plus the usual slight background from inevitable radioactive inclusions. Random association of tracks yielding 'spurious' events was therefore greatly reduced and could be virtually eliminated by measurement of a range of distributions of tracks in the emulsion.

In a study of 50,000 binary events in these emulsions the following types of event have been recorded:

(1) 179 cases have been observed of ternary fission into two heavy fragments and a long-range α-particle; the frequency is 1 per 280 (± 25) spontaneous binary fissions. The mode appears to be significantly more frequent than in the case of slow-neutron fission of uranium-235, uranium-233 or plutonium-239 (ref. 8). An example is shown in Fig. 1.

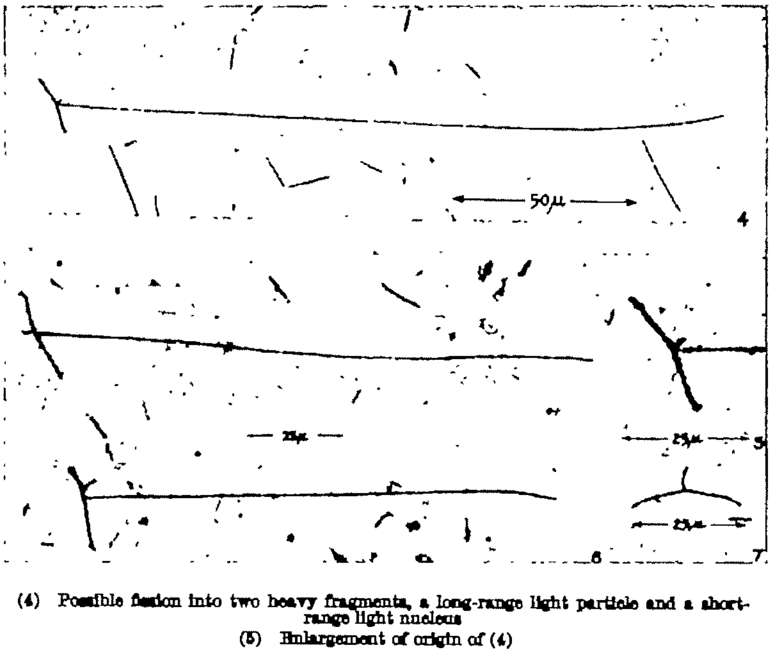


(1) Ternary fission of californium-252
(2) Probable quaternary fission of californium-252
(3) Projection of recoils in emulsion shortly after fission giving appearance similar to a quaternary fission

(2) Eight good examples and four additional possible cases of fission into four heavy fragments (Fig. 2) have been observed. Apart from quaternary fission, the only other possible explanation for these events is that they arise from recoils projected in the emulsion by the pair of fission fragments within $\frac{1}{2}\mu$ of the origin. Two experimental results oppose such an explanation. Although events of this general type do occur (as is indicated by Fig. 3 but where the 1μ spacing between the forks clearly eliminates the event as quaternary), their observed frequency is too low to explain the four-particle events. Moreover, if scattering accounted for such events, then in the earlier study of 600,000 uranium-235 binary fissions[4], some 100 such events should have been observed; in fact only 2 were recorded. We therefore believe the events to be true spontaneous quaternary fission, the frequency being roughly 1 per 5,000 binary fissions.

(3) Three events of the type Fig. 4 (and see enlargement of origin, Fig. 5) have been observed. Again these might be explained as an event of type 1 with a recoil occurring near the origin, and such spurious cases do occur as indicated in Fig. 6. However, during our earlier work where more than 10^6 binary fissions were examined, only one other example of such an event was observed. These events may, therefore, represent a mode of spontaneous quaternary fission involving emission of a long-range α-particle and a short-range light nucleus in addition to the two fission fragments.

(4) As in previous experiments, a considerable number of events are observed which could be interpreted as ternary fission, the third fragment being a short-range light nucleus. The frequency of occurrence of such tracks at the origin appears to be greater than would be expected from Rutherford scattering. In addition to these events, which occur at a rate of 1 per 80 (± 20) binary fissions, others have been observed which could be ternary fission into three roughly equal parts. Analysis of the type employed by Catala *et al.*[6] indicates that many of these arise through fission fragments colliding with silver or bromine nuclei in the emulsion. However, it does not exclude all and it could be that this mode of fission exists in californium-252.



(4) Possible fission into two heavy fragments, a long-range light particle and a short-range light nucleus

(5) Enlargement of origin of (4)

(6) Examples of a ternary event of type (1) with a recoil track close to origin, easily distinguishable from (4)

(7) Case of possible ternary fission into three roughly equal fragments

The experiments are continuing, and will be reported in detail later. We wish to thank Prof. E. M. McMillan and Dr. S. G. Thompson, of the University of California, who provided the californium for these experiments.

The Second Virial Coefficient of Methane at Low Temperature

THE second virial coefficient of methane has been determined over a range of temperatures from 108° to 350° K. by means of an apparatus which is described elsewhere[1].

The principle of the experiments consists in measuring the difference in the expansion of volume of the gas under study and a reference gas. In our experiments we chose hydrogen as reference substance. The working pressure is less than one atmosphere; this allows us to neglect coefficients of higher order than the second in the expansion of the compressibility factor pV/nRT, where p is pressure V, is volume, R is the gas constant, T is absolute temperature and n is number of moles.

Methane was obtained by distillation at low temperature of commercial 'pure grade' gas. The melting of the solidified sample we used took place over a range of less than 1×10^{-3} °K. The vapour pressure at the triple point was 87·58 mm. mercury. The value of 87·60 ± 0·10 mm. mercury was found at the National Bureau of Standards of Washington by Armstrong, Brickwedde and Scott[2] with a carefully purified sample. The purity estimated from the range of freezing point was better than 99·8 per cent (ref. 3). The hydrogen used was 'research grade' gas of 99·99 per cent purity.

Values obtained for methane are listed in Table 1. In Fig. 1 these values are reproduced for compari-

smooth aggregat

gth of the bond between
wn aggregate surfaces
t of the paste matrix.
r example in the case
in concrete containing
egate bond is likely to

be the factor controlling strength. Although several aspects of the mode of failure of concrete could be explained by this concept, it was soon clear that a number of others which should also have been explained were, in fact, anomalous. The form of the departures from expected behaviour suggested that cement-aggregate bond-strength might depend on aggregate size, and the following experiments were therefore performed to check this possibility.

Cubes of water-saturated basalt-aggregate, with edge-lengths ranging from 0·5 to 3·0 in., were bonded to a paste of ordinary commercial Portland cement, cured for 24 hr. in the moulds at 70° F., and afterwards stored under water at 70° F. for six days. Cement paste, with a water/cement ratio of 0·35 by weight, was bonded to the aggregate cube face to be tested, while the opposite face, previously grooved with a diamond saw, was bonded to paste with a water/cement ratio of 0·31. These conditions ensured preferential failure at the interface between aggregate and the 0·35 water/cement ratio paste when the composite beam was subjected to mid-point loading as shown in Fig. 1. The beam was immersed in water during testing[2], and the number of replications ranged from 20 for the ½-in. cubes, down to 10 for the 3-in. cubes. The mean coefficient of variation was 15 per cent.

The results (Fig. 2) show that with the square aggregate surfaces used here, bond-strength decreases with increasing size of aggregate, and that there is a linear relationship between cement-aggregate bond-strength and the logarithm of the reciprocal of the area bonded.

Although coarse aggregate and mortar are frequently considered to be the two phases of which concrete is composed it has also been argued that if the bond between cement paste and coarse aggregate is likely to fail, then the bond to fine aggregate would also fail, and that the two phases to be considered are cement paste and all aggregate, regardless of size. These alternative hypotheses have been debated in discussions[3,4] on the mode of failure of concrete and, in this connexion, it might be thought that extrapolation of the present results back to the point where bond-strength equals paste-strength (in the present case 2,000 lb./in.[2]) would decide between these two points of view. Such an extrapolation leads to the conclusion that bond failure ceases to be the most likely cause of tensile failure of concrete when the aggregate size falls below 14 B.S.S. mesh. However, the results of additional experiments suggest that the rate at which bond-strength increases with decreasing aggregate size is not maintained below ½-in. aggregate, although experimental difficulties in this region have so far prevented an accurate assessment of the situation.

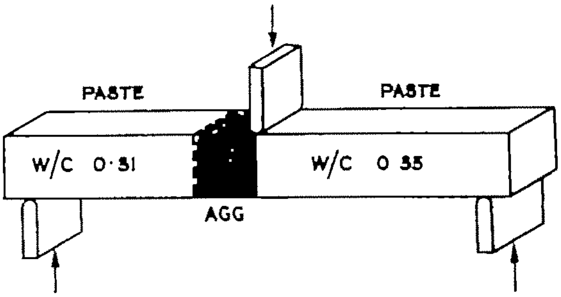

Fig. 1

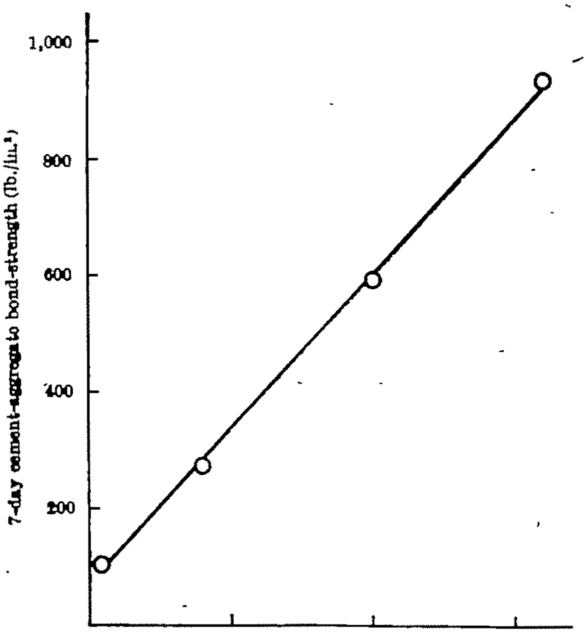

Fig. 2

Thus, instead of favouring the view that the transition size between coarse and fine aggregate has special significance in the phenomenon of failure in concrete, or the alternative view that bond is equally likely to fail at the surface of either coarse or fine aggregate, the present results indicate that there are likely to be specific zones of weakness in concrete, and that these zones are located at the junction between the paste matrix and the largest aggregate pebbles present. With this hypothesis as a basis, explanations can be advanced for a number of experimental observations concerning the strength of concrete, for example:

(1) The flexural strength of concrete is less than the flexural strength of the corresponding mortar[4]. This result would be expected because, in the transition from concrete to mortar, the weakest bonds have been eliminated by exclusion of the largest aggregate pebbles.

(2) In an investigation[5] on the strengths of concretes containing coarse aggregate with maximum sizes ranging from ⅜ to 2½ in. it was found that in spite of the progressive reduction in mixing water requirement as maximum size of coarse aggregate increased, increasing the maximum size of aggregate above ¾ in. did not necessarily increase either flexural or compressive strength. Lowest strengths were in fact obtained with concrete containing 2½ in. maximum size aggregate. These effects are apparently caused by introducing areas of exceptionally weak cement-aggregate bond, as a consequence of increasing the maximum size of aggregate in the mix.

(3) In the investigation[5] mentioned in (2) the reproducibility of strength tests was found to be poorest for concrete containing the largest maximum size of aggregate. The dependence of cement-aggregate bond-strength on aggregate size could explain this behaviour as follows. Taking an extreme case, such as that of specimens used for flexural strength tests on mixes containing the largest pebbles, it is apparent, first, that these large pebbles, which develop the weakest cement-aggregate bond, will be relatively few in number, and secondly, that whether or not a cement-aggregate interface on one of the large pebbles is suitably orientated and in that part of the beam which is in maximum tension, could have an appreciable effect on the strength of the specimen, and could be the cause of the poor reproducibility of these particular tests.

A possible reason for the bond-strength size effect is that in cement paste the process of hardening may be accompanied by dimensional changes which are large enough to give rise to considerable internal stress in the paste film in contact with the aggregate surface, when this tendency of the paste to move is opposed by the aggregate. The larger the surface bonded, the greater the internal stress and the smaller the apparent bond-strength. A rather similar situation applies in the case of the restraint which different sizes of aggregate exert on Portland cement paste during drying shrinkage[6].

For a number of reasons it is considered that the bond-strength size effect in concrete will probably not be as marked as that shown by isolated cement-aggregate interfaces such as those studied here. For example, near the region where maximum tensile stress exists in a beam tested in flexure the orientation of the largest aggregate surfaces may be such that these comparatively weak areas of cement-aggregate bond are subjected only to low tensile stress. Also, the largest aggregate pebbles are not embedded in neat cement paste, but in a matrix the dimensional changes of which are likely to be reduced by the stabilizing influence of the smaller pebbles and sand grains which it contains.

A Historical Note on the Reciprocal Theorem and Theory of Statically Indeterminate Frameworks

OPINIONS seem to vary concerning the origin of the reciprocal theorem. Thus, in his book "Mathematical Theory of Elasticity" (4th edit. 1927), A. E. H. Love attributed the theorem to E. Betti (*Il nuovo Cimento*, ser. 2, 1872), but stated that it is a special case of a more general theorem due to Lord Rayleigh (*London Math. Soc. Proc.*, 4, 1873). In his book "Theory of Sound" (Vol. 1, 2nd edit. 1894), however, Rayleigh also acknowledged the reciprocal theorem as due to Betti. Neither Love nor Rayleigh connected Maxwell's name with the theorem although it is widely known as "Maxwell's Reciprocal Theorem". In fact, Maxwell did include a statement of a form of the reciprocal theorem in his paper "On the Calculation of the Equilibrium and Stiffness of

Frames" (*Phil. I*). It is, no doubt, due
to this work, whi efore the relevant work
of Betti and Ray well is nowadays given
credit for the the interesting to note the
neglect of Maxw Rayleigh and Love.

Another autho rk, in retrospect, had
some bearing u iprocal theorem was
A. Clebsch (18 , although Clebsch's

A Possible xo-Electron Emission in Pl formed Metals

THE blackening c ographic emulsions
by freshly fracture surfaces was first
studied in detail by 97[1]. This phenom-
enon, the Russell v known to be a
consequence of the hydrogen peroxide
on the freshly ex surfaces[2]. More
recent work by Gr ted that the form-
ation of hydrogen initiated, in the
presence of water va en, by the emission
of low-energy exo-e s emission received
considerable attenti ber of Continental
workers[3], and it is epted that in the
case of metals the electrons are emitted from crystal imperfections in the freshly formed or distorted oxide layer.

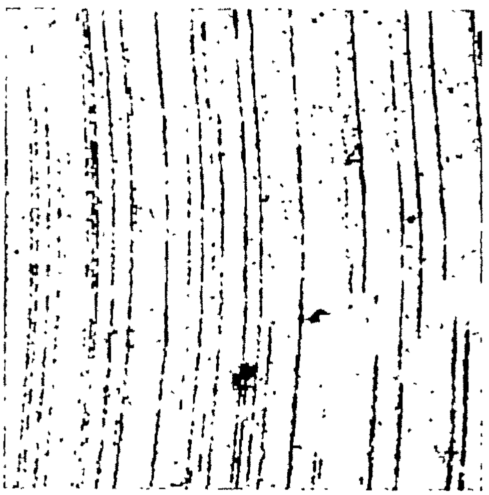

Fig. 1. The appearance of exposed emulsion at low magnification. Lines correspond to slip lines on the crystal surface. (× 140)

So far, only the macroscopic or integrated aspects of both the Russell effect and exo-electrons have been studied. We have observed, by the use of an autoradiographic stripping emulsion of high resolution, certain microscopic features of the Russell effect which may be useful in revealing the origin of both phenomena. The improved image resolution obtained by this technique was made possible by placing the emulsion in intimate contact with the metal surface.

High-purity zinc single crystal rods were electropolished, thoroughly cleaned, statically strained and the emulsion (Kodak *AR*10 stripping emulsion) then applied to the surface. Exposure times of 1 hr. were generally found adequate, provided the exposure was commenced within a few minutes of straining. On examination of the emulsion with an optical microscope, black lines were observed which corresponded exactly to slip-lines on the crystal surface. An example is shown in Fig. 1. Since the slip displacement varied around the circumference of the crystal, it was possible to deduce that the continuous black

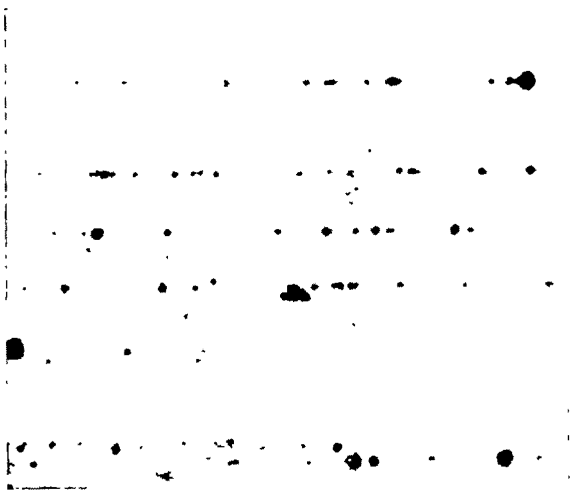

Fig. 2. Pattern obtained from slip lines of small displacement. Maximum useful magnification of emulsion. (× 940)

lines were associated with relatively large slip displacement. With decreasing slip displacement the lines first became discontinuous and then resolvable into rows of individual spots (Fig. 2). This latter configuration resembles the dislocation etch pits observed by one of us[6] along the slip lines of zinc single crystals.

The foregoing evidence shows that the Russell effect, and probably exo-electron emission, in plastically deformed metals originate from slip bands on the surface. The similarity between the patterns observed here and dislocation etch pits configurations further suggests that the centres of emission are the points where dislocations terminate at the surface of the crystal. It is possible that at such points the oxide film is highly distorted by the emergence of the dislocation, thus producing the imperfections necessary for exo-electron emission. This hypothesis is further supported by recent work reported by Young[7], who has shown that oxide nuclei are formed at dislocations.

The hypothesis is in agreement with previous observations that both the rate of exo-electron emission and the intensity of the Russell effect increase with increasing deformation[8]. It would be interesting to make a comparison of the rate of emission from two crystals of widely differing dislocation concentrations.

Correlation of the Alternating Stresses required to initiate and propagate a Fatigue Crack in Mild Steel

EXPERIMENTAL results obtained from mild steel plates containing small edge cracks subjected to reversed direct stress loading (that is, zero mean load) have suggested that whether or not a crack grows is governed by the parameter $\sigma^3 l$ (σ = nominal alternating stress, tons/sq. in., l = length of edge crack, inches)[1]. If the value of $\sigma^3 l$ is greater than 5·5, a crack will grow; if less, it will remain dormant. It has been shown[1–4] that with certain notched specimens, non-propagating cracks may be present at the root of the notch of those tested at stresses equal to and below the conventional notched fatigue limit (that is, for specimens either remaining unbroken or being completely broken). When the geometry of the specimens is such that non-propagating cracks are present, the conventional notched fatigue limit is independent of the radius of the notch root and is equal to the alternating stress required to propagate the crack. This depends on the depth of the notch, for it has been shown[1] that the relationship $\sigma^3 l = 5\cdot5$ is applicable if l is taken as the depth of notch plus the length of non-propagating crack formed.

It is generally accepted that at zero mean load the fatigue strength of a notched specimen is greater than that given by the plain fatigue limit of the material divided by the geometric elastic stress concentration factor for the notch. Many attempts, usually related to the existence of the stress gradient at the root of the notch, have been made to account for this discrepancy; however, ignorance of the possibility of non-propagating cracks has led to much confusion. Isibasi and Uryu[4], however, differentiated between crack initiation and propagation; they found that for mild steel notched specimens, cracks formed at the root of the notch when the distribution of stress was such that over a distance of 0·002 in. in from the root of the notch the stresses were equal to or greater than the plain fatigue limit.

For zero mean load the material at the root of a notch is subjected to similar stress distributions on the tension and compression halves of the loading cycle; the material ahead of a crack, however, is subjected to stress concentration effects only on the tension half of the cycle. Thus when considering the intrinsic fatigue strength of the material ahead of a crack, the zero to tension value is appropriate. For the mild steel under consideration, this value is about 0–22 tons/sq. in. The yield stress of the material is about 19 tons/sq. in., and thus measurement of the plastic zone ahead of the crack in a plate specimen will give an approximate estimate of the length of material subjected to stresses greater than the plain fatigue limit. Frost and Dugdale[5] made such measurements on annealed (furnace-cooled from 800° C.) mild steel sheet specimens and found for the initial period of growth that the length of the plastic zone (l_p) was directly proportional to the current length of crack (l), that is, $l_p = Cl$; l_p and l were measured from the centre line of the specimen. I have shown[1] that C could be empirically related to the nominal stresses by the equation:

$$C = 1 + 0\cdot0013\sigma^3$$

where σ was the maximum tensile stress in the loading cycle. For the mild steel plate specimens used to determine the $\sigma^3 l = 5\cdot5$ relationship, it appears reasonable to assume a similar type of relationship, namely:

$$C = 1 + K\sigma^3$$

Estimates have been made of the length of the plastic zone developed ahead of a fatigue crack by applying a static tensile load to cracked fatigue specimens; high nominal stresses were imposed, so that measurable plastic zones resulted. An example is shown on Fig. 1. Taking measurements from the outside edge of the plate, that is, including the depth of the notch, $l_p = 0\cdot50$ in. and $l = 0\cdot28$ in.; thus $C = 1\cdot8$. The nominal stress applied was 13 tons/sq. in., giving $K = 0\cdot00036$. If λ is the length of plastic zone measured from the tip of the crack, then:

$$\lambda = l_p - l = 0\cdot00036\sigma^3 l$$

and substituting $\sigma^3 l = 5\cdot5$ will give the value of λ which must be subjected to stresses equal to or greater than the plain fatigue limit before the crack will grow; hence $\lambda = 5\cdot5 \times 0\cdot00036 = 0\cdot002$ in. This agrees with the value obtained by Isibasi and Uryu[4] from notched specimens.

Fatigue cracks in plain specimens are known to start on the surface, and metallographic examination

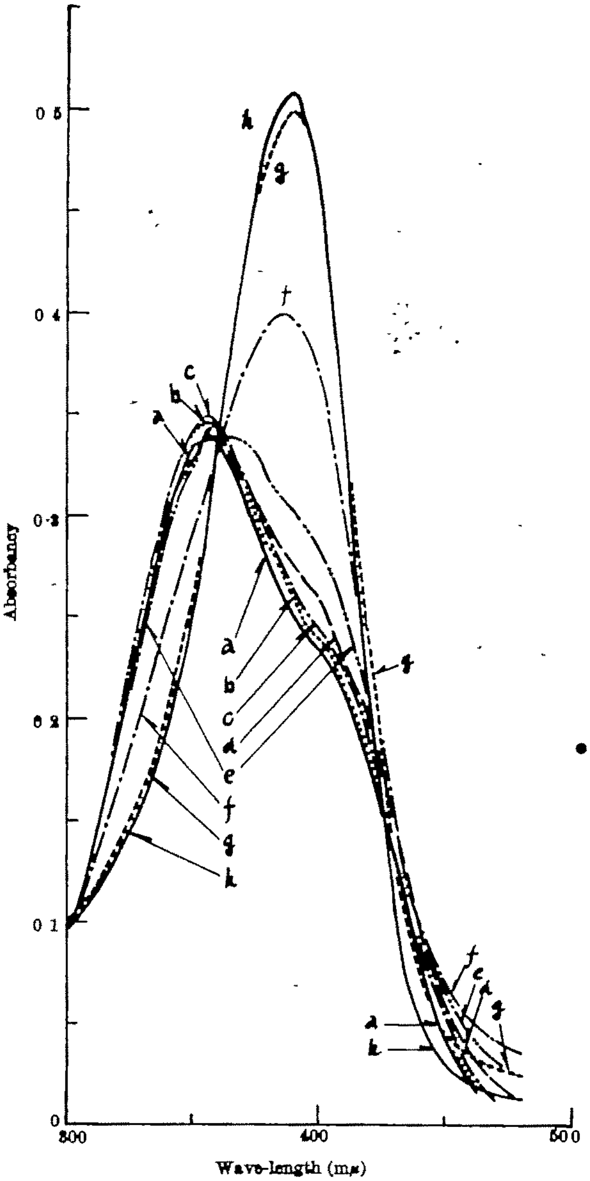

Fig. 1. Absorption spectra of aqueous solutions of picric acid ($2 \cdot 42 \times 10^{-5}$ *M*) at various concentrations of sodium hydroxide at 20° C. (path-length of cells, 1 cm.). Concentrations of sodium hydroxide: *a*, 0; *b*, 0·206 *N*; *c*, 0·411 *N*; *d*, 1·03 *N*; *e*, 1·44 *N*; *f*, 2·06 *N*; *g*, 3·09 *N*; *h*, 4·11 *N*

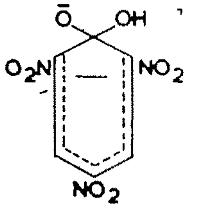
hydroxide is due mainly to picrate anion. The absorbancy of the 360-mμ band of picric acid slightly increases at low concentrations of sodium hydroxide up to 0·411 *N* and then decreases at concentrations of sodium hydroxide higher than 0·411 *N*. The increase in the absorbancy at 360 mμ can be interpreted as being due to nearly complete dissociation of picric acid, caused by sodium hydroxide. On the other hand, absorbancy at about 390 mμ increases with the increasing concentration of sodium hydroxide. The absorption curves of the solutions at the higher concentrations of sodium hydroxide over 2·06 *N*, showing the sharp and intense bands at about 390 mμ, are greatly different from those of the solutions with the low concentrations of sodium hydroxide. Accordingly, the intense 390-mμ band, the absorbancy of which decreases slowly when the solution is stood at room temperature for long days, cannot be ascribed to picrate anion.

When 1,3,5-trinitrobenzene and its derivatives in water are treated with sodium hydroxide, red solutions are immediately formed.' These red colours have been ascribed to complexes such as [trinitrobenzene·OH]⁻ (refs. 1 and 2). It has been reported by Kimura[3] that picric acid in a mixture of acetone and ethanol gives an intense 410-mμ band and a weak 485 mμ one when a drop of sodium hydroxide solution is added, owing to formation of [picric acid.CH_2-$COCH_3$]⁻. The intense 390 mμ band of picric acid in aqueous concentrated solution of sodium hydroxide may be expected to be due to a complex of [picrate anion·OH]⁻, which seems possibly to be the ion (I) of Meisenheimer's type[4].



(I)

The spectra were measured with a Hitachi *EPU*-2 spectrophotometer.

I wish to thank Prof. Y. Nomura for helpful discussions.

Generation of Aerosols by Vapour-Phase Polymerization of Methyl Acrylate

THIS particle generator made by us is the outgrowth of work by Melville[1], in which he studied the photopolymerization of methyl acrylate and methyl methacrylate vapour at low pressures in a closed chamber in which no other gas was present. On irradiation with ultra-violet light in the 2500-Å. region, a fairly dense cloud of particles is formed in the chamber. The ultra-violet light activates the monomer and small nuclei are formed, that is, a few molecules of polymer on which the remaining monomer gas can react. Once the reaction is initiated, it will continue without further irradiation.

We have found that this process can also be carried out in a flow system (Fig. 1) at atmospheric pressure so long as oxygen is excluded. Ordinary cylinder nitrogen gas was passed over freshly distilled monomer and mixed with a larger volume of nitrogen gas. It then entered a quartz tube of 3 cm. internal diameter where a beam of ultra-violet light was focused on it from a Hanovia type *A*, 500-W. high-pressure mercury arc lamp. The gas flowed past the light source at 0·1–0·5 cm./sec. Visible aerosols that exhibited higher-order Tyndall spectra were produced, indicating a fair degree of monodispersity. The methyl acrylate gave solid particles, while the methyl methacrylate produced liquid particles. Neither materials seemed to be stable in the electron microscope, but dark-field microscopy showed uniform particles ranging from 0·1 to 2·0μ, depending on the concentration of vapour and rate of flow.

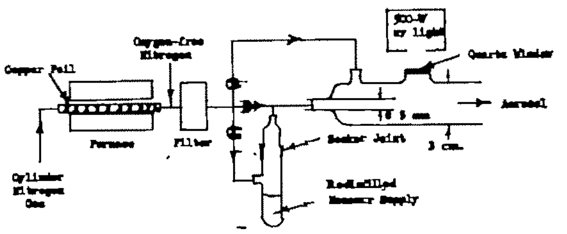

Fig. 1. Methyl acrylate particle generator

The most difficult problem was the formation of polymer on the walls of the quartz tube, which prevented the short-wave radiation from reaching the monomer vapours. Some work was done with a vapour-free gas sheath to keep the polymer off the wall. However, due to the low rate of production of particles and the other problems mentioned above, the work was discontinued in favour of other devices for the production of homogeneous aerosols of sub-micron dimensions.

The work is presented here in the hope that it may stimulate others, who are not confronted by immediate practical needs, to follow up on this rather interesting variation on aerosol generators.

We acknowledge the guidance of Dr. S. Katz, who suggested this approach to the problem. The work was supported by the Air Force Cambridge Research Center, Bedford, Massachusetts (Contract No. *AF* 19(604)-2411), as part of a programme on electrostatic size classification of sub-micron aerosols.

Determination of Nonanol Residues in Potatoes

A NEW method for the destruction of potato sprouts in the course of potato storage is ventilating with air containing nonanol in the amount of 0·1 mgm. per litre[1]. By applying this British method in our country we were very interested in the determination of nonanol in the ventilation air as well as in the potatoes after being treated in this way. The nonanol used is the branched isomer 3,5,5′-trimethylhexanol-1, produced by Imperial Chemical Industries, Ltd.

For the determination we use Feigl's spot test for the alcoholic hydroxyl group using the reagent vanadium oxinate[2] quantitatively, as has also been discussed by others[3–5]. We are applying this reaction using solid vanadium oxinate as reagent in a toluenic solution of nonanol.

The reagent vanadium oxinate is prepared by mixing a solution of 15 gm. 8-hydroxyquinoline in 600 ml. acetic acid (6 per cent) and a solution of 2·3 gm. sodium meta-vanadate ($NaVO_3.4H_2O$) in 600 ml. water. After 1 hr. the precipitate is filtered

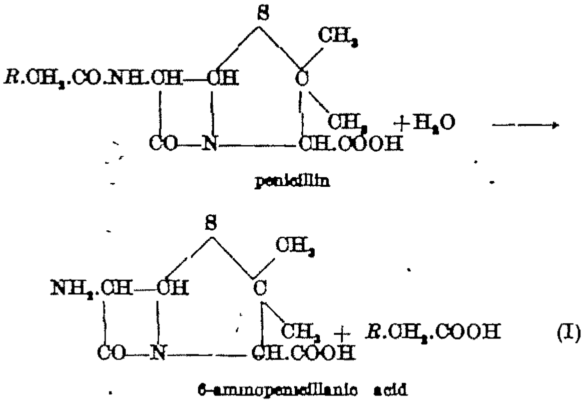
BIOCHEMISTRY

Formation of 6-Aminopenicillanic Acid from Penicillin by Enzymatic Hydrolysis

WE have found that enzymatic activity which brings about reaction (1) is fairly widespread among micro-organisms:



Sakaguchi and Murao[1], and later Murao[2], originally reported this type of enzyme activity to occur in *Penicillium chrysogenum* with penicillin *G* as substrate. Although we have been unable to confirm such activity in *P. chrysogenum* with penicillin *G* as substrate, with certain other penicillins, including penicillin *K*, such activity can be demonstrated.

Among the micro-organisms at least two distinct types of enzyme activity are encountered which bring about reaction (1). These differ primarily in the type of penicillins serving as substrate. One type is widely distributed among the actinomycetes and filamentous fungi and is also present in certain yeasts. With this type of enzyme, penicillin *K* and dihydro-*F* and also penicillin *V* are readily hydrolysed, but penicillin *G* is split only very slowly. Compared with penicillin *V*, penicillin *G* is only hydrolysed at about 1 per cent of the rate. Studies on this enzyme produced by a strain of *Streptomyces lavendulae* show that the activity is almost entirely extracellular with a *p*H optimum in the region of 9·0 and a temperature optimum of about 50° C. The enzyme can be precipitated with ammonium sulphate and dried as an acetone powder with little loss of activity. Enzyme formation does not appear to be induced by growing in the presence of the substrate.

The other type of activity has only been detected among the bacteria and appears to be largely confined to the genera *Escherichia* and *Alcaligenes*, but activity has also been detected in certain other genera. With any given species there is a high degree of strain specificity with regard to enzyme formation. With this type of enzyme, penicillin *G* is hydrolysed very readily, whereas penicillin *V* is only split at about 20 per cent of this rate. When penicillin *G* is used as substrate with cells of a strain of *Escherichia coli* which have been centrifuged and then resuspended at twice their original density, a concentration of 2 per cent penicillin *G* can be converted to 6-aminopenicillanic acid to 95 per cent of completion in 4 hr. Studies with a strain of *E. coli* show the *p*H optimum for this enzyme to be 7·5–8·5 with a temperature optimum of about 40° C. With the species of *Escherichia* the enzyme activity is usually associated with the cells but with other bacteria considerable activity may occur extracellularly. As with the enzyme produced by the actinomycetes and moulds there is no evidence of induced enzyme formation.

In addition to the hydrolysis of penicillin to give 6-aminopenicillanic acid, this enzyme also facilitates the reaction in the opposite direction so as to bring about the synthesis of penicillin from 6-aminopenicillanic acid and a suitable side-chain. Using a strain of *E. coli* the optimum *p*H for penicillin *G* synthesis from 6-aminopenicillanic acid and phenylacetic acid is about 5·5, in contrast to an optimum of about 8·0 for hydrolysis. The synthetic reaction is also favoured, as might be expected, by increased concentration of 6-aminopenicillanic acid. Reaction in the direction of synthesis shows a similar specificity with regard to the type of penicillin as does the hydrolytic reaction.

We acknowledge our appreciation of valuable discussions with Dr. J. Farquharson, director of research, and to the Board of Beecham Research Laboratories, Ltd., for permission to publish.

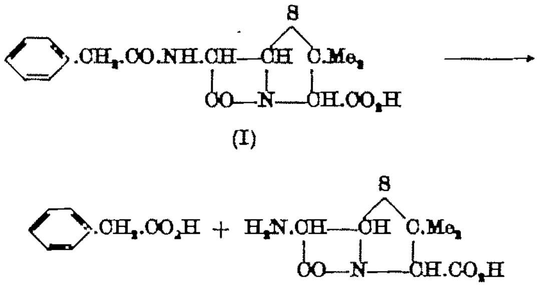
Bacterial Penicillin Amidase

Sakaguchi and Murao[1] reported on the presence of an enzyme in the mycelium of *Penicillium chrysogenum* and *Aspergillus oryzae* which would split penicillin *G* (I) into phenylacetic acid (II) and 'penicin' (III):



(I)

(II) (III)

Although they offered no rigorous proof of structure, they postulated that 'penicin' was the compound formed. In the nomenclature of Sheehan *et al.*[2], 'penicin' is termed 6-aminopenicillanic acid. We have attempted to reproduce the work, but have not been able to detect even small amounts of (III). Batchelor *et al.*[3] demonstrated the presence of (III) in penicillin fermentations which were carried out in the absence of added side-chain precursor. (III) was detected by activation of the fermentation liquor with phenylacetyl chloride after removal of the natural penicillins by solvent extraction at low *p*H. This resulted in the formation of (I), which could be measured by standard bacterial inhibition assays.

We wish to report upon the formation of (III) from (I) through the action of a penicillin amidase prepared from cells of *Alcaligenes faecalis*. A preliminary survey was first made of cultures in an attempt to demonstrate the presence of this amidase. Under the conditions used, traces of (III) were produced from (I) by cells of *Aerobacter cloacae*, *Bacillus subtilis* var. *niger*, *Micrococcus lysodeikticus*, and *Mycobacterium phlei*. Much greater amounts were detected when *A. faecalis* was used, and further work was concentrated upon this organism.

The standard amidase assay used consisted of growing the cells for 18 hr. at 27° C. on a rotary shaker, collecting cells by centrifuging 20·0 ml. of broth, and adding 0·5 ml. of an 80 mgm. per ml. solution of the potassium salt of (I) in 0·1 *M* *p*H 7·5 potassium phosphate buffer plus sufficient of the same buffer to bring the volume to 2·0 ml. The reaction mixture was incubated in a 37° C. water-bath with intermittent shaking for 4 hr. The supernatant was then assayed for (III) by treatment with phenylacetyl chloride[3] and bioassaying the (I) formed by a plate diffusion assay.

That (III) was the product formed was proved by its isolation in crystalline form from a large-scale reaction mixture. (III) was identified by comparison with the authentic compound using chemical and infra-red analyses.

The specificity of the enzyme was tested by comparison of activity using penicillins *G*, *K* and *V* and α-phenoxyethyl penicillin as substrates. The production of (III) was greatest from (I). To ensure that permeability barriers did not account for the specificity, a cell-free enzyme preparation was made and its specificity again tested. Cells of *A. faecalis* grown in Difco heart infusion broth were exposed for 30 min. in a 10 kc./s. Raytheon sonic oscillator. The debris was removed by centrifugation in the cold at 12,000*g* for 30 min. The activity of this cell-free extract was tested for production of (III) from the various penicillins (Table 1). It can be seen that the same order of activity is obtained with both preparations. The soluble preparation was not tested on α-phenoxyethyl penicillin.

The ability of the enzyme to catalyse the reverse reactions was tested by adding to a mixture of cells and (III), sodium phenylacetate, sodium phenoxyacetate, and sodium caproate. Measurable amounts of (I) and penicillin *K* but not of penicillin *V* were formed under the conditions of the experiment (Table 2). A similar experiment with α-phenoxypropionic acid and (III) failed to reveal any synthesis of α-phenoxyethyl penicillin. The specificity of the synthesis approximates that of the reverse reaction, indicating that the same enzyme is involved.

Almost complete conversion of (I) to (III) could be obtained at lower levels of (I) and longer incubation

day, when concentrations up to 2 mgm. per ml. (calculated as lysergic acid) were reached. An excess of oxygen in the culture fluid was essential for production of alkaloid.

The bases were extracted from the filtered culture media at pH 7·2–7·4 with organic solvents and transferred to water (by extraction with diluted acids). The alkaloids were then concentrated by repeating this procedure several times, and finally recovered from the organic solvent phase as the free bases or the maleates.

Four main substances were obtained which were recognized as two pairs of isomers, deriving from lysergic and *iso*lysergic acid respectively.

The members of the first pair of isomers were both obtained in the crystalline state and identified as lysergic acid amide (*iso*ergine[3]) and *iso*lysergic acid amide (ergine[4]); their decomposition points, crystal form, chromatographic behaviour and infra-red spectra were identical with the corresponding properties of authentic specimens. On hydrolysis with N sodium hydroxide, lysergic acid amide gave ammonia and lysergic acid in good yield; the lysergic acid thus obtained was identical in all respects with an authentic specimen derived from natural ergot. The mixture of both pairs of alkaloids on hydrolysis with N sodium hydroxide gave ammonia and lysergic and *iso*lysergic acid, which were identified chromatographically. On treatment with anhydrous hydrazine or hydrazine hydrate[5], lysergic acid amide as well as *iso*lysergic acid amide gave racemic *iso*lysergic acid hydrazide in good yield; the latter was identified by its infra-red spectrum.

The members of the second pair of alkaloids yielded readily one molecule of acetaldehyde and one molecule of ammonia on treatment with diluted mineral acids in the boiling water-bath. The lysergic acid derivative was easily transformed into lysergic acid amide, with concomitant evolution of acetaldehyde, at pH 8 and 50°. The latter reaction occurs slowly even on standing at room temperature. The isomer derived from lysergic acid was obtained in the crystalline state as the free base from chloroform and as the acid maleate from methanol–ether. The free base was obtained in long solvent-free prisms which started to decompose at 135° C. (Kofler) and showed $[\alpha]_D^{20°}$ + 29° ± 2° (C = 1 in dimethylformamide) and no appreciable rotation in pyridine. Its ultra-violet spectrum was identical with that of other amide-substituted derivatives of lysergic acid (maxima at 242 and 312 mμ). The infra-red spectrum is shown in Fig. 1.

Analysis (free base): calculated for $C_{18}H_{21}N_3O_2$ (311·37). C, 69·43; H, 6·80; N, 13·50. Found: C, 69·23; 69·30; H, 6·94–7·04; N, 13·69.

Analysis (maleate): calculated for $C_{18}H_{21}N_3O_2.C_4H_4O_4$ (427·44): C, 61·81; H, 5·90; N, 9·83. Found: C, 61·80; H, 6·33; N, 9·87.

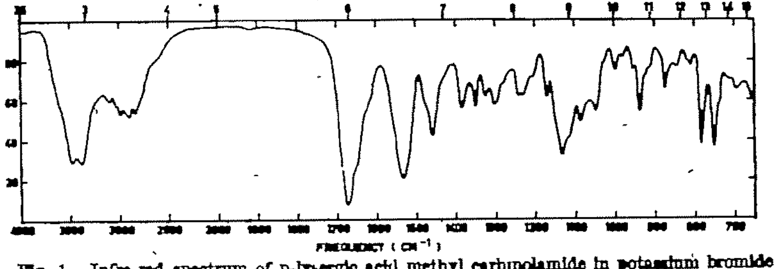

Fig. 1. Infra-red spectrum of D-lysergic acid methyl carbinolamide in potassium bromide (C = 0·3 per cent)

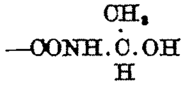
The second member of the pair of isomers, derived from *iso*lysergic acid, was not obtained in the crystalline form; but by isomerization with diluted acetic acid, it was readily transformed into the isomer obtained from lysergic acid described above.

The two lysergic acid derivatives yielding acetaldehyde are thought to have the acetaldehyde moiety linked to the lysergic acid moiety in the form of the carbinolamido linkage:



$$\begin{array}{c} \mathrm{CH_3} \\ \text{—CONH.}\overset{|}{\mathrm{C}}\mathrm{.OH} \\ \mathrm{H} \end{array}$$

Neither the two isomers of lysergic acid amide nor those of lysergic acid methyl carbinolamide have previously been reported to occur in Nature.

Full details of this work will be published elsewhere.

Microbial Synthesis of Protein in Relation to the Biogenesis of Nucleic Acids with *Azotobacter vinelandii* as the Test Organism

Caspersson[1] and Brachet[2] first directed attention to the possible role of ribonucleic acid in protein synthesis. This role has been re-evaluated by Brachet and Six[3]. Ribonucleic acid is supposed to serve as a template for protein synthesis. Evidence in favour of and against this hypothesis has been documented by Chantrenne[4], Meister[5], Simkin[6] and Hartman and Buchanan[7].

One of the most useful tools in demonstrating the relationship between protein and nucleic acid syntheses is to use antibiotics and antimetabolites which interfere with either one or both the processes[1–6]. The mechanism of incorporation of radioactive amino-acids into protein of particulate preparations of *Azotobacter vinelandii* is being investigated in detail in this laboratory. As a prelude to that work, the effect of some antibiotics and antimetabolites on the synthesis of nucleic acid and of protein in whole cells of *A. vinelandii* has been studied. Similar effects have been observed in cell-free preparations as well.

Disodium hydrogen phosphate (^{32}P) and sodium sulphate (^{35}S) were found to be rapidly incorporated into the growing cells of *A. vinelandii*. The fraction soluble in trichloroacetic acid attained saturation with either tracer, phosphorus-32 or sulphur-35, within about an hour, whereas incorporation into the fractions insoluble in trichloroacetic acid maintained a steady rate of incorporation in parallel with the growth of the cells. The resting cells of *A. vinelandii* similarly incorporated phosphorus-32 and sulphur-35 at a comparatively good rate. As in the case of growing cells, a source of energy, for example sucrose, was needed for the incorporation of both the tracers into the resting cells. Analyses of the fractions insoluble in trichloracetic acid showed that 90 per cent. of the phosphorus-32 was incorporated into nucleic acids, whereas 97 per cent of the sulphur-35 was incorporated into protein. Thus the incorporation of phosphorus-32 and sulphur-35 into the fractions insoluble in trichloracetic acid of the resting cells can be looked upon as reflecting protein and nucleic acid syntheses respectively.

The results of inhibition studies of the incorporations of phosphorus-32 and sulphur-35 into resting cells of *A. vinelandii* in the presence of antibiotics and antimetabolites are presented in Table 1. The detailed kinetic results will be presented elsewhere. The concentrations of the inhibitors chosen are three times those required for inhibition of growth.

Table 1. EFFECT OF ANTIBIOTICS AND ANTIMETABOLITES ON THE INCORPORATION OF PHOSPHORUS-32 AND SULPHUR-35 INTO THE NUCLEIC ACIDS AND PROTEIN OF THE RESTING CELLS OF *A. vinelandii*

Antibiotic or antimetabolite used	Inhibition of incorporation (per cent)*	
	Phosphorus-32	Sulphur-35
Chloramphenicol (600 μgm./ml.)	5	90
Streptomycin (400 μgm./ml.)	45	90
Penicillin (114 μgm./ml.)	15	54
p-Fluorophenylalanine (720 μgm./ml.)	17	36
8-Azaguanine (600 μgm./ml.)	13	71

* Percentage inhibitions have been calculated with reference to the incorporation of the tracers into the fractions of the control insoluble in trichloracetic acid containing no antibiotic or antimetabolite, which was 400 counts/min. in the case of phosphorus-32 and 375 counts/min. in the case of sulphur-35.

In experiments on the incorporation of phosphorus-32, incubation was at 30° C. for 2 hr. with constant shaking in a total volume of 10 ml. containing 610 μmoles of sucrose, 42 μmoles of radioactive potassium phosphate, *p*H 7·0 (2·4 × 10^6 counts/min.), 150 mgm. (on dry weight basis) of cells of *A. vinelandii* and a suitable amount of growth inhibitor or antimetabolite (see Table 1). For the incorporation of sulphur-35, conditions were exactly the same with the exception that 23 μmoles of radioactive sodium sulphate (2 × 10^6 counts/min.) were added instead of phosphate. Non-radioactive phosphate buffer (42 μmoles) was, however, included. Control incubations without any antibiotic or antimetabolite were always run. Incorporation was stopped by quick centrifugation at 20,000*g* followed by washings; the cells were washed four times, each time with 10 ml. of 0·05 *M* phosphate or 0·05 *M* sulphate respectively. Washed cells were treated with 1 ml. of cold 10 per cent trichloracetic acid for 30 min. The precipitate collected by centrifugation was re-treated with [illegible] ml. of cold 5 per cent trichloracetic acid. Finally, the precipitate was washed twice in each case with 10 ml. of 0·05 *M* phosphate (or sulphate) and suspended in 10 ml. of water. Aliquots were plated, dried and counted in a thin-window Geiger counter (Nuclear Chicago Co.). Since the plating was done at infinite thinness, no self-absorption correction was needed.

Incorporation of phosphorus-32 into nucleic acids is affected only to a small extent in the presence of chloramphenicol. Protein synthesis as reflected by incorporation of sulphur-35 is, however, inhibited to a great extent as expected. Streptomycin similarly interferes with incorporation of sulphur-35. Incorporation of phosphorus-32 is also inhibited to a considerable extent. Penicillin, which is known to

Flavonoid Pigments of *Lathyrus odoratus*

ALTHOUGH the genetics and chemistry of flower colour variation in the garden sweet pea, *Lathyrus odoratus*, have been much investigated[1], none of the pigments present has yet been fully characterized. As part of a general study of flavonoid production in garden plants[2–4], these pigments have now been analysed by means of paper chromatography and absorption spectrophotometry. Since the sweet pea varieties used by earlier investigators were not available, comparable colour forms were chosen from the wide range of present-day varieties. Examination by chromatography divided them into three main classes, depending on whether their anthocyanins were derived from the orange pelargonidin, the magenta cyanidin or the mauve delphinidin. Three deeply pigmented varieties, 'Air Warden', 'Harrow' and 'Jupiter', representing respectively each of these colour classes, were chosen for detailed examination since they contained the greatest number of pigments.

Table 1. OCCURRENCE OF FLAVONOIDS IN SWEET PEA COLOUR VARIETIES

Variety	Anthocyanins	Flavonol glycosides
'Air Warden' scarlet cerise (also other varieties: orange and salmon shades)	pelargonidin 3-rhamnoside 5-glucoside-3-rhamnoside* 3-glucoside 3-xylosylglucoside 3 · 5-diglucoside	kampferol 3-rhamnoside*
'Harrow' deep carmine (also other varieties pink and rose shades)	cyanidin and peonidin 3-rhamnoside 5-glucoside-3-rhamnoside* 3-glucoside 3-xylosylglucoside peonidin 3 : 5-diglucoside	kampferol and quercetin 3-rhamnoside*
'Jupiter' deep purple (also other varieties lilac, mauve and blue shades)	delphinidin and petunidin 3-rhamnoside delphinidin, petunidin and malvidin 5-glucoside-3-rhamnoside*	kampferol, quercetin and myricetin 3-rhamnoside*

* Major glycosides; minor flavonol glycosides not shown.

Nineteen anthocyanins and three flavonol glycosides were isolated and identified by means of methods already described[2]. Their distribution is indicated in Table 1. Paler-coloured varieties generally contained the same pigments as the intensely coloured types though in less amount, except that the anthocyanidin 3-rhamnosides were completely lacking. Five white varieties which were examined contained the same flavonol glycosides as either 'Air Warden' or 'Harrow'; a myricetin-containing white form equivalent to 'Jupiter' was not found. Besides the three flavonol 3-rhamnosides shown in Table 1, several other flavonol glycosides were present in small amounts in most varieties. Three (that occurred with kampferol 3-rhamnoside in the white variety 'Valerie') were kampferol derivatives which had two or more sugar residues, of which one, at least, in each case was rhamnose. 'Valerie' also contained the cinnamic acid related to kampferol, namely, *p*-coumaric acid. It was present esterified both with glucose and with a rhamnosylglucose (probably rutinose). The glucose ester is the same compound that has recently been identified in potato berries[5] and flowers of *Primula obconica* (Corner, J. J., and Harborne, J. B., unpublished work); the other ester has not yet been described.

The presence in *Lathyrus* of two new series of anthocyanidin glycosides (that is, the 3-rhamnosides and 5-glucoside-3-rhamnosides) is noteworthy since the 3-substituted sugar, in almost all the known anthocyanins, is glucose. The new pigments have much higher R_F values than the corresponding glucosides in all the usual solvent systems. Furthermore, they are much more resistant than 3-glucosides and 3 : 5-diglucosides to hydrolysis by fungal anthocyanase (see ref. 6); the 5-glucoside-3-rhamnosides, for example, gave good yields of the corresponding 3-rhamnosides after incubation for 2 hr. with excess enzyme at 37° C. and *p*H 3·9.

Glycosides of all six common anthocyanidins are, with one exception, represented in both the new series: the exception is malvidin 3-rhamnoside which has, however, been provisionally identified on the basis of R_F values in wild *Lathyrus sativus*, following the observation (Pecket, R. C., private communication) that an unusual malvidin derivative was present in that species. Pecket found that other species of *Lathyrus* (including a wild *L. odoratus*) contained only 3-glucosides. The present discovery of as many as five different kinds of glycoside in the sweet-pea shows that domestication has had a very marked effect on pigment synthesis in this species. The only other plant known to contain anthocyanin mixtures as complex as these is *Streptocarpus* (which is of hybrid origin[4,7]).

In disagreement with an earlier report[1], related anthocyanidins and flavonols occur together in all the varieties examined. This agrees with findings in *Solanum phureja*[3] and a number of other plants[3,4]. The genes *E* and *Sm*, which control hydroxylation of the anthocyanidins in *Lathyrus*, evidently also determine the flavonol hydroxylation pattern. Since flavonols and anthocyanidins are both present as 3-rhamnosides, it is likely that the same enzyme controls the addition of this sugar to both kinds of pigment. The addition of the other sugar residues must, however, be controlled by enzymes which exhibit a greater degree of substrate specificity. These results thus provide additional evidence of the close biosynthetic relationship that exists between flavonols and the anthocyanidins and of the great complexity of pigment glycosidation that occurs in highly evolved garden plants.

Ferricyanide Reduction Method for Reducing Sugars

THE ferricyanide reduction method and its modifications[1-3] for the determination of reducing sugars are among the more commonly used techniques for this purpose. They depend on the spectrophotometric measurement of the amount of prussian blue formed when excess ferric iron is added to the reactant mixture.

As prussian blue forms an unstable, hydrophobic colloidal sol, protective agents, generally hydrophilic colloids, are added to keep it from flocculating. Gum ghatti[1,3], gum arabic[2], or 'Duponol'[3] is generally used. When added in excess they adsorb on the hydrophobic prussian blue, reversing the charge and stabilizing the sol.

However, the above-mentioned protective agents have several defects. The gums contain reducing materials which must first be oxidized with potassium permanganate; in addition, if the amount of glucose or other reducing sugar present in the aliquot is greater than 150–200 μgm., the resultant prussian blue frequently flocculates in spite of the protective agents, preventing accurate measurement. 'Duponol' thickens the reactant mixture, and great care must be taken to avoid the introduction of small air bubbles which tend to remain suspended.

Although oxalic acid has long been known to peptise prussian blue sols[4,5], its use does not seem to have been attempted in connexion with the ferricyanide method for reducing sugars. Its use is described in this communication.

The method followed was that of Folin and Malmros[1] as modified by Umbreit, Burris and Stauffer[3]. However, gum ghatti was omitted from the ferric iron solution. After heating the glucose–ferricyanide mixture in a boiling water bath for 15 min. and cooling, 5 ml. of ferric iron solution and then 1 ml. 0·8 per cent aqueous oxalic acid solution were added rapidly. The volume was made up to 25 ml. with distilled water, and after standing 15 min. the optical density at 520 mμ was measured with a Beckman *DU* spectrophotometer. A reagent blank was prepared and all determinations were in duplicate.

Fig. 1 indicates that Beer's law is obeyed up to 300 μgm. of glucose. The reactant solution appeared perfectly clear when observed with the unaided eye or a microscope, even after standing for 1–2 hr. When gum ghatti or gum arabic was used as a stabilizer, microscopic aggregates could be seen after 10–15 min., and frequently flocculation occurred rapidly. The use of one-fifth as much oxalic acid also resulted in flocculation after 15 min., while if more than 1 ml.

r (4:1) and 2.4.6
: 1). Analysis was

carried out on 15 μl. urine; a similar volume of an oxidized specimen was run at the same time. Papers were developed with ninhydrin and spots identified by the position to which they ran and their colour reaction with ninhydrin[2], and by running pure samples of amino-acids with the urine specimens in some instances.

Some 6–9 spots were usually detected, the three strongest and most consistent being methyl-histidine, taurine and felinine. Glycine and alanine were variably present; the other spots were unidentified. Methyl-histidine was present in each cat's urine on each diet. It has been suggested that it derives from ingested anserine[3] and has been identified in large quantities in the urine of several carnivores, including that of domestic cats[3]. Taurine disappeared from the urine of both male cats on the two lowest protein diets, when all the animals were in negative nitrogen balance[1], and from the urine of both females collected at the end of the period on the 13 per cent protein diet. After this period all the cats were placed on high-protein diets and taurine reappeared in all urine specimens. Felinine (cystein-S-isopentanol)[4] was almost always present in the unoxidized specimens, often producing the strongest spot. It was never present after oxidation: if this was carried out by hydrogen peroxide in the presence of ammonium molybdate[3] a spot in the position normally occupied by cysteic acid invariably occurred; if by hydrogen peroxide alone a brownish spot appeared close to methyl-histidine (with an R_F value slightly less in phenol, slightly greater in collidine/lutidine). Datta and Harris[3] in no case found both felinine ('cat spot') and taurine occurring in quantity in the same urine, and suggested on the results of dietary experiments that felinine is synthesized in the body from cysteine which would otherwise be further metabolized to taurine, this synthesis being encouraged by some component of cod-liver oil. However, it is shown in the experiment reported here that both taurine and felinine may be excreted in considerable quantity at the same time, but that on diets providing less than the minimum concentration of protein necessary to maintain nitrogen equilibrium (21 per cent dry weight in this experiment[1]) felinine may be excreted preferentially to taurine. It has been suggested[5] that felinine may be formed in the cat kidney (where it may exist in a bound form) and be excreted directly; only traces were detected in plasma and bladder tissue, and none in kidney, liver, brain or gastrocnemius, whereas in cat urine its concentration was estimated as 185 mgm. per cent[5]. Recently, leucine labelled with carbon-14 and mevalonic acid have been shown to participate in felinine biosynthesis in the cat[6].

We are indebted to Dr. S. Trippett for a sample of 'natural' felinine, and to Messrs. Petfoods, Ltd., for a grant.

Restoration of Membrane Excitability of Calcium-deficient Muscles by Anodal Polarization

It is well known that marked electrophysiological and biochemical disturbances occur in nerve and muscle immersed in calcium-free Ringer's solution[1]. In the present experiment, isolated frog (*Rana pipiens*) sartorius muscles were used. When they were soaked in calcium-free Ringer solution (112 m*M* sodium chloride ; 2 m*M* potassium chloride ; 2·4 m*M* sodium bicarbonate), initial hyper-excitability was followed by a loss of excitability. This effect of calcium deficiency was enhanced by adding ethylenediaminetetraacetic acid to the medium. In calcium-free Ringer containing 4 m*M* ethylenediaminetetraacetic acid, muscles twitch while the resting potential rapidly drops to 50–30 mV. within an hour. As usual, the electrical activity which ordinarily accompanies stimulation was completely but reversibly eliminated in the 60–120 min. following immersion. This loss of excitability cannot be explained simply by the reduction of the resting potential, since a number of fibres showed, transiently, a relatively high resting potential in spite of a loss of excitability[2]. Whether excitability was maintained depended on the susceptibility of individual fibres ; even a seasonal variation being apparent. For example, the electrical activity of some muscles disappeared instantaneously in calcium-free Ringer, particularly in spring frogs. This seems to suggest that excitability depends on the properties of the membrane *per se*, which may be altered by the presence or absence of calcium ions.

This concept was supported by the following experimental results on muscle fibres registering complete loss of excitability and reduced resting potential (40–20 mV.) in calcium-free Ringer solution (with or without ethylenediaminetetraacetic acid). In these fibres, it was possible to restore the electrical excitability by applying anodal polarization to the membrane, as Fig. 1 shows. Here, one microelectrode in a muscle fibre recorded the membrane potential, and another microelectrode in the same fibre passed both polarizing and stimulating currents. Repetitive anodal square pulses initiated 'break responses' above a critical level of hyperpolarization (record 3). If cathodal stimulations were applied during the passage of these anodal pulses, the action potentials were induced at a certain threshold level (record 2). The spike had higher magnitude during continuous anodal polarization (record 2). A certain magnitude of hyperpolarization and a certain period of passage of the current were necessary for production of action potentials.

In calcium-free Ringer solution, muscle apparently gains sodium and loses potassium (Miyamoto and Koketsu, unpublished observation). Neither reduction of intracellular potassium nor accumulation of potassium in the interfibre space seems to be directly responsible for reducing resting potential and excitability. As a matter of fact, in the present experiments, washing with calcium-free Ringer solution did not restore excitability.

The experiment described here clearly demonstrates that calcium ions in the external solution are not immediately necessary for the production of action potentials (for the opposite conclusion see ref. 3). So far as membrane property was maintained in the excitable state by applying anodal polarization, the membrane was capable of producing action potentials without external calcium. Thus, the loss of electrical activity of the membrane in calcium-free Ringer solution cannot be explained simply by the absence of external calcium ions. Presumably, changes in the physico-chemical property of the membrane resulting from withdrawal of the external calcium are responsible for the loss of membrane excitability. We found a serious disturbance in the metabolic energy supply (Abood and Koketsu, unpublished work) and also in the distribution of sodium, potassium, calcium, and magnesium ions (Miyamoto and Koketsu, unpublished work) when sartorius muscles were soaked in calcium-free Ringer solution with or without ethylenediamine tetraacetic acid.

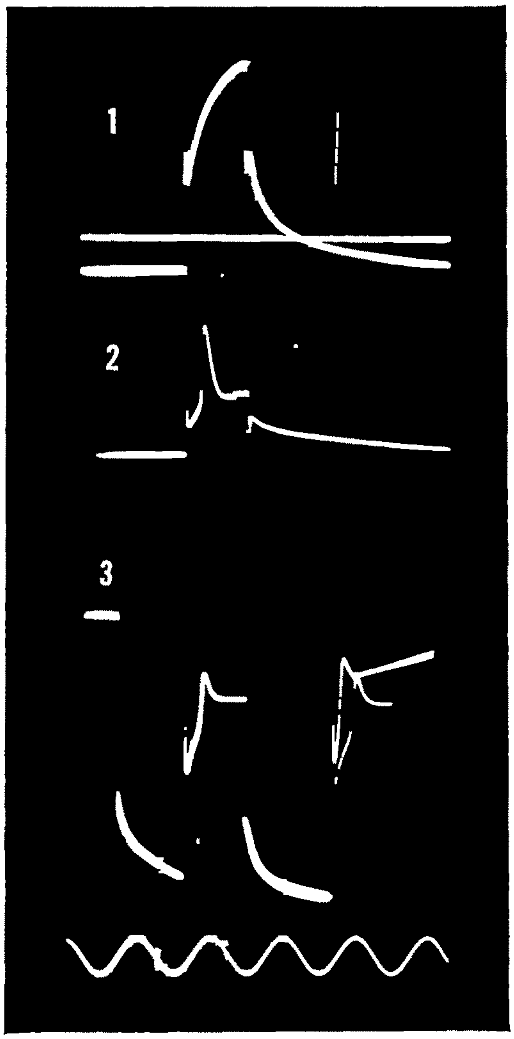

Fig. 1. Restoration of action potentials by anodal polarization of depolarized membrane in calcium-free Ringer solution. All records were obtained from the same muscle fibre, which gave no responses even to strong cathodal stimulation while resting potential was strongly depolarized (record 1, interval of two beams shows value of resting potential). Record 2 is action potential produced by cathodal stimulation when membrane potential was raised to about 100 mV by continuous anodal polarization. Record 3 shows 'break responses' produced by anodal pulses, and also responses produced by cathodal pulses during passage of anodal pulses. Records 1 and 2 are single sweeps, and in record 3 three traces were superimposed with a time interval of 10/sec. Vertical line is 50 mV., and time mark is 100 cycles/sec.

An important problem is to determine whether these biochemical and biophysical disturbances are responsible for the loss of excitability. We may assume that short-lived anodal currents do not affect such

events ; and ther

metric titration with $0 \cdot 001\ N$ ethylenediaminetetraacetic acid after removal of phosphate with an ion-exchange resin[4]. Murexide was used as indicator for the calcium titration (pH 12–13) and Eriochrome Black for the calcium plus magnesium titration (pH 10·0–10·5)[5].

Fig. 1 shows the mean calcium, magnesium and citric acid contents of the various sections of the oviducts of 5 hens. The magnum showed little variation in composition throughout its length, and single figures for the whole of this region are recorded. The most remarkable feature of this graph is the close relationship between the calcium and citric acid in the different sections of the isthmus and uterus. It is well known that tissues such as bone and dentine and secretions such as milk and seminal plasma are rich in both calcium and citric acid, but so far as we are aware, the extremely close parallel between these two cell constituents which we have observed in the hen's oviduct has not been reported in other tissues. The correlation coefficient, r, between calcium and citric acid for the 65 sections of the isthmus and uterus of the 5 hens was found to be $+ 0 \cdot 97$. The regression equation calculated from these data is :

$$y = 0 \cdot 237x + 17 \cdot 7$$

where y = mgm. calcium./100 gm., x = mgm. citric acid/100 gm.

From this equation it may be calculated that for each m.mole increase in citric acid there is an increase of 1·14 m.mole calcium.

The physiological significance of the extremely high level of citric acid in the isthmus is quite obscure. This region is about 10 cm. long and the distal half contains at least 300 mgm. citric acid/100 gm. fresh tissue. It is in this section of the oviduct that the shell membranes are laid down, but so far as is known, shell calcification does not occur until the uterus, which contains very much less calcium and citric acid, is reached.

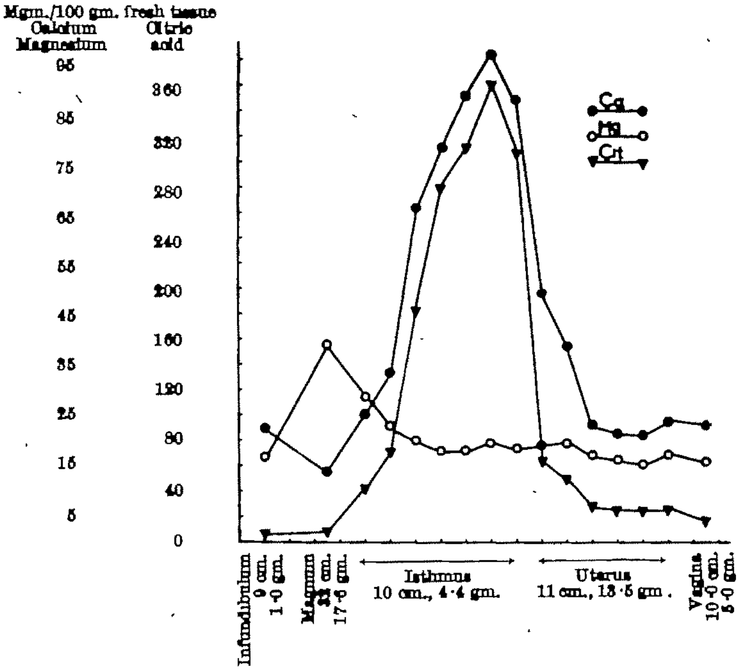

Fig. 1. Mean concentrations of calcium, magnesium and citric acid in the different sections of the oviduct of the hen, and mean lengths and weights of the sections

We have found that the concentration of citric acid in the isthmus is not altered in birds injected with fluoroacetate, and the enzymes of the Krebs cycle which seem most likely to be implicated in the high citric acid content of this region are under investigation.

The tubular region of the uterus adjacent to the isthmus, the isthmo-uterine junction[6], is considerably richer in calcium and citric acid than the thick muscular region where the main process of shell calcification occurs, and this may be due to the fact that the transition from isthmus to uterus is gradual, there being no definite histological boundary between the two regions[7].

Magnesium forms a complex ion with citrate[8] similar to that formed between calcium and citrate; but in spite of the large variations in citric acid in the different segments, the magnesium content of the isthmus and uterus is constant at a level of 15–20 mgm./100 gm. The magnum, however, which is relatively low in citric acid (less than 10 mgm./100 gm.) contains approximately twice as much magnesium (38 mgm./100 gm.) as any other region of the oviduct.

We wish to thank Dr. B. C. Saunders for a generous gift of sodium fluoroacetate.

Oxytocin in the Neurohypophysis of the Laying Hen

ALTHOUGH it has been well known that the administration of posterior lobe hormones induces premature oviposition in the hen, *Gallus domesticus*[1,2], as in other fowls[3], it remains undetermined whether the hormone(s) plays an essential part in normal oviposition. The results presented here may throw light on the mechanism of oviposition in the domestic fowl.

Twenty-five White Leghorn hens in their first year of production were killed at the following times: (1) 3–4 hr. before expected oviposition; (2) within an hour before expected oviposition; (3) within 5 min. after oviposition; (4) 1–2 hr. after oviposition; (5) 5–6 hr. after oviposition. The posterior lobes of the hypophysis of each bird were extracted with 0·25 per cent acetic acid immediately after removal, and assayed for oxytocic activity against 'Pitocin' (Parke, Davis and Co.) on the isolated uterus of an oestrous virgin rat of Wistar strain, following Holton's method[4]. Dibenamine and atropine were added to the organ-bath.

Fig. 1 shows the mean hormone content per lobe and its 95 per cent fiducial limits. The differences between the lobes removed within 5 min. after oviposition and those removed at other times were significant ($P < 0·01$). These differences were not materially affected by using other criteria of comparison; for example, hormone content per milligram neurohypophysial tissue. No significant difference was found between the weights of the posterior lobes.

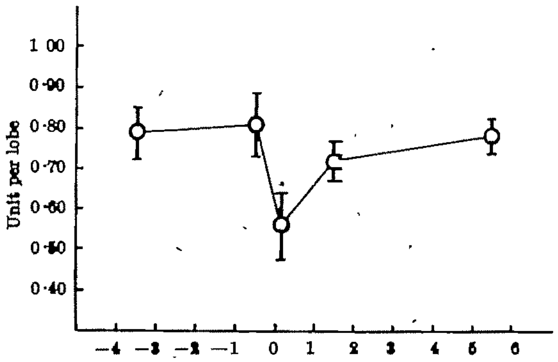

Fig. 1. Oxytocic hormone content in the posterior lobe of the hypophysis before and after oviposition. Each circle represents the mean value of determinations made on five hens. The vertical lines represent the fiducial limits of the mean (degree of confidence, 0·95)

It would appear then that oviposition in the hen follows depletion of oxytocic hormone from the posterior lobe, and that the hormone accumulates in the hypophysis soon after oviposition.

Hunger Reduction produced by Injecting Glucose into the Lateral Ventricle of the Rat

IT has been repeatedly shown that the ventromedial nucleus of the hypothalamus is responsible for the satiation of hunger. According to Mayer[1], this is brought about by hypothalamic glucoreceptors. Because of the rapid removal of injected glucose from the blood-stream, direct experimental tests of Mayer's hypothesis have yielded conflicting results.

The technique of intraventricular injection employed in the present experiment is a modification of that developed by Feldberg and Sherwood[2] for use on cats, and details will be published elsewhere. In brief, a stainless steel cannula is stereotaxically implanted and permanently fixed in the lateral ventricle, and the animal is allowed to recover from the anaesthetic. Correct positioning is checked by injecting the satiated rat with a small quantity of 2 per cent saline through the cannula. If the cannula tip is in the ventricular system, the injected fluid reaches the hypothalamic osmoreceptors and the animal responds by drinking water. The validity of this test has been confirmed at autopsy by injecting a dye through the cannula.

The unrestrained animals are injected with an electrically driven micrometer syringe connected to the cannula by polythene tubing at a rate of 0·005 ml./min., to a total volume of 0·2 ml./kgm. body-weight. Such injections *per se* do not appear to

Excitation at the Crayfish Neuromuscular Junction with Decreased Membrane Conductance

THE generally accepted mechanism of chemical transmission at excitatory and inhibitory synapses is an interaction of a transmitter substance with the sub-synaptic cell region, causing an increase of membrane conductance for specific ions. Excitatory transmission is essentially a depolarization due to the increased membrane permeability to one or more ions (predominantly Na^+) which have their effective 'electrochemical equilibrium' potential near zero membrane potential. This system has been worked out most thoroughly in the vertebrate nerve–muscle junction by Katz, Fatt and Del Castillo[1]. An interesting variation of the above postsynaptic mechanism is described here.

In a 'slow' crayfish muscle, stimulation of the motor axon at 75/sec. causes excitatory junctional potentials which facilitate and sum, building up to a plateau. The conductance of the membrane was determined by passing a short constant hyperpolarizing current pulse across the membrane of the fibre and measuring the resulting change in electrotonic potential. This was done at rest (lower trace, Fig. 1*A*) and during the plateau phase (upper trace). The electrotonic potential during excitation is decreased, showing the increase in conductance which is expected from analogy with other synapses. If the same experiment is repeated with the Ca^{++} level raised to four times normal (56 m*M*/l.) in the external medium the resting conductance is only little altered (less than 5 per cent), as seen in Fig. 1*B*. During the excitatory junctional potential plateau, however, with a somewhat smaller depolarization than in Fig. 1*A*, the applied current pulse results in an electrotonic potential which is more than 150 per cent of the control in the resting fibre. The membrane conductance, therefore, must have greatly decreased during excitatory transmission.

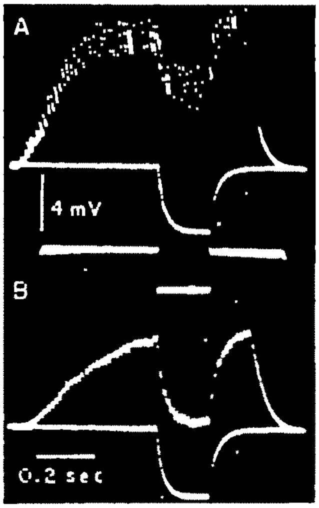

Fig. 1. Intracellular recordings from a muscle fibre in the abductor of the dactyl in the first walking leg of the crayfish (*Orconectes virilis*). In *A* and *B* two sweeps are superimposed, in the upper the excitatory nerve is stimulated at 75/sec., in lower fibre at rest. Trace between *A* and *B* measures current pulse (2·5 × 10^{-8} amp.) passed across membrane in each sweep through the second electrode. Ca^{++} in bathing solution in *A* is normal, in *B* is raised four-fold to 56 m*M*/l.

The following interpretation is offered: During an excess of Ca^{++} the observed conductance decrease is due to the decreased permeability to ions with an equilibrium potential near the resting potential, or more negative than the resting potential. K^+ and/or Cl^+ are the only known ions which fulfil this requirement.

It is thought that Ca^{++} excess does not cause the observed conductance decrease, but merely unmasks it by reducing the larger increase in sodium permeability which normally swamps and obscures the conductance decrease of K^+ and/or Cl^-. In support of this thesis it was seen that the normal excitatory junctional potential actually does not behave as if it were due to a conductance increase to an ion (or ions) with an 'equilibrium potential' near zero. We have found that during hyperpolarization of the resting membrane the excitatory junctional potential does not increase proportionally, as expected if it were purely of the conductance increase type. This had also been observed earlier[2], but the deviation from the predicted curve was attributed to a conductance increase caused by the hyperpolarizing current itself. Such an interpretation seems excluded in the present experiments. Furthermore, in the presence of Ca^{++} excess the excitatory junctional potential may actually decrease during hyperpolarization. Under these conditions one may even expect a reversal of the excitatory junctional potential at large negative resting potentials. This, however, could not be demonstrated experimentally even when the membrane potential was increased from − 80 to − 180 mV.

The following events are thus thought to occur at crustacean junctions: The excitatory transmitter combines with receptor sites at the junctional areas causing simultaneously two types of permeability changes. (1) An *increase* in membrane conductance predominantly to Na^+. (2) A *decrease* in conductance to K^+ and/or Cl^-. Both permeability changes cause depolarization and thus their effects are additive.

A Second Mechanism of Inhibition at the Crayfish Neuromuscular Junction

IN crayfish muscle fibres single stimulation of an inhibitory axon sets up small inhibitory junctional potentials (Fig. 1*A*). Fatt and Katz[1] showed that such inhibitory potential changes are caused by an increase of the membrane conductance to ions (K^+ and/or Cl^-) with an 'electrochemical equilibrium' close to the resting potential. This equilibrium potential can readily be determined. For example, in the experiment of Fig. 1*E* short trains of depolarizing inhibitory potentials were repeated every 2 sec. Beginning at the arrow, the membrane was depolarized progressively by passing a current across it. The inhibitory potentials became smaller and eventually reversed their polarity at the equilibrium level. A basically similar mechanism has been found in all inhibitory synapses studied so far, for example, in motoneurons, the atrium of the heart and in stretch receptor neurons of the crayfish[2]. Here an additional mechanism is reported.

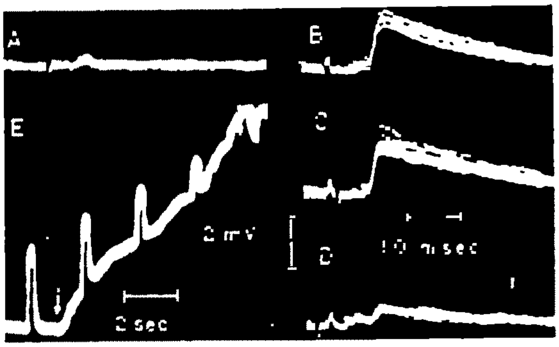

Fig. 1. Potentials recorded during one insertion of an intracellular electrode from a crayfish muscle fibre (adductor of the dactyl in the first walking leg of *Orconectes virilis*). Resting potential 80 mV. *A* to *D*. Single stimuli repeated 5/sec., several sweeps superimposed. *A*, inhibitory junctional potential. *B*, excitatory junctional potential. *C*, inhibitory plus excitatory potential, inhibitory stimulus 1 msec. after excitatory stimulus. *D*, inhibitory plus excitatory potential, inhibitory stimulus 3 msec. before excitatory stimulus. Time calibration 10 msec. for *A* to *D*. *E*, trains of inhibitory stimuli at 150/sec. repeated every 2 sec. At arrow start of membrane depolarization by passing current through second electrode. Broken line at 6 mV. depolarization indicates equilibrium potential of inhibition. Time calibration 2 sec. for *E*, voltage calibration 2 mV. for *A* to *E*

In the experiment of Fig. 1 the resting potential is about 6 mV. more negative than the inhibitory reversal potential, as shown in Fig. 1*E*. The size of the excitatory junctional potential in Fig. 1*B* is less than 3 mV., that is to say, it does not reach the inhibitory reversal potential. If now the conductance increase mechanism described above is the only mediator of inhibition, in this experimental situation the inhibitory potential should add to the excitatory potential and not reduce it. This, in fact, is the case in Fig. 1*C* where the timing is set so that the inhibitory potential (cf. Fig. 1*A*) falls on the peak of the excitatory one (Fig. 1*B*). However, if in Fig. 1*D* the inhibitory potential precedes the excitatory by 3 msec., the excitatory potential is greatly reduced in size. The timing is quite critical (cf. also ref. 3); in this experiment the effect is maximal for an interval 2–3 msec. Such an inhibitory effect cannot be explained by the increase of conductance mechanism, and therefore in addition a second mechanism of inhibition has to be postulated. This could be either a postsynaptic interaction between the inhibitory and excitatory transmitter substances, for example, in a competitive manner[1], or the inhibitor could influence the presynaptic excitatory nerve.

There is no direct method of studying the presynaptic nerve endings, but indirectly the state of excitatory facilitation and the frequency of spontaneous miniature potentials reveal presynaptic conditions. During the first second after a conditioning period of excitatory stimulation at high frequencies a burst of spontaneous miniature potentials is recorded in the muscle fibre[4], and for several seconds the size of single excitatory potentials is greatly increased as the result of presynaptic facilitation. This post-excitatory facilitation as well as the increase of frequency of miniature potentials is reduced if during the conditioning period inhibitory stimuli precede the excitatory ones by 2–3 msec. (as in Fig. 1*D*). If, however, the excitatory and inhibitory impulses are more separated no effect on post-

, rinsed in water,

dehydrated in ethanol, cleared in xylol and mounted in balsam or synthetic medium. (After rinsing with distilled water a light blue nuclear staining, for example Weigert hæmatoxylin, may be used. This, however, will somewhat reduce the brightness of the histochemical staining.)

The incubating medium is prepared as follows:

To 20 mgm. of sodium α-acid phosphate (Dajac Lab., Philadelphia), dissolved in 13 ml. distilled water + 5 ml. of Michaelis veronal–acetate buffer stock solution (9·714 gm. sodium acetate $3H_2O$ + 14·714 gm. sodium barbiturate in distilled water free from carbon dioxide, made up to 500 ml.), 1·6 ml. of 'hexazonium salt' solution is added. The hexazonium salt solution is prepared freshly by mixing in a test tube equal amounts (0·8 ml.) of these two stock solutions: (*a*) 4 per cent pararosanilin hydrochloride (*C.I.* 676, National Aniline Division, Allied Chemical and Dye Corporation, New York) in 2 *N* hydrochloric acid, and (*b*) 4 per cent sodium nitrite[7]. The *p*H of the medium is then adjusted by *p*H-meter to 6·5 with 1 *N* sodium hydroxide (about 0·6 ml.). After this the solution is filtered into a Coplin jar and is ready for incubation. The veronal–acetate buffer can be replaced by phosphate or *tris*-maleate buffers.

It is assumed that the diazotization of *p*-rosaniline (triphenylaminomethane) results in the formation of hexazonium salt[1] capable of forming dyes with one, two or eventually three azo groups. The assumption that different compounds are formed is supported by the observation that the colour of azo dye varies with the *p*H. The colour is reddish in acid *p*H, becoming brownish towards neutral *p*H. Further treatment with naphthols results in changes in colour of both the reaction product and of the background staining, suggesting the presence of free diazo groups in the azo dye formed. These free diazo groups, able to form complexes with proteins, may in this way contribute to the insolubility of the azo dye, thus improving the localization. The fresh hexazonium salt is stable enough at acid *p*H to permit incubation at room temperature without change of the incubating medium for 60 min.

The hexazonium pararosanilin seems not significantly to inhibit the acid phosphatase at acid *p*H. However, quantitative data are not available. At neutral or alkaline *p*H the inactivation of acid phosphatase is considerable, indicating a diazonium-type reaction between the hexazonium pararosanilin and the enzyme. When stable diazonium salts are used the inhibition of enzymes is by most authors ascribed to the stabilizer. At acid *p*H the hexazonium salt does not cause appreciable changes in staining for adenosine triphosphatase or 5-nucleotidase, thus permitting combination with these techniques. The excess nitrous acid in the fresh diazonium salt solution seems not to interfere with the staining. Addition of urea to the incubating medium, in order to eliminate the excess of nitrous acid, did not change the histochemical pattern. However, most of the excess nitrous acid can be removed from the hexazonium salt solution by vacuum.

The naphthyl phosphate hexazonium pararosanilin method was employed at *p*H 6·5. This *p*H, chosen empirically, represents a necessary compromise between adequate azo-coupling and optimum enzyme activity. The coupling-rate of hexazonium pararosanilin with α-naphthyl is sluggish between *p*H 4·5 and 5·5. It increases towards neutral *p*H and permits good histochemical localization at *p*H 6·5 or above. Even at pH 6·0 or below the localization is better than with other diazonium salts. On the other hand, the acid phosphatase(s) of tissues examined so far are active at these pH. In the case of rat liver, acid phosphatase activity at pH 6·5 represents about 50 per cent of activity measured at pH 5.

The improved localization given by this technique is attributed to the insolubility and substantivity of the azo-dye formed. The dye is resistant to most of the organic solvents and is insoluble in lipids. It is amorphous or microcrystalline. Its colour and form did not change in mounted slides in 10 months. It gave reproducible, constant results in large series of sections of human, rat and mouse tissues. The applicability of this method to nervous tissue, both animal and human (Anderson, P., unpublished observations), deserves emphasis. It should stimulate the re-evaluation of the distribution of acid phosphatase in nervous tissue, where the results with the Gomori lead method are most questionable. It is hoped that the simple modification described will facilitate the histochemical study of the physiological and pathological significance of the somewhat neglected acid phosphatase.

This work was supported by Grant No. *A*–1783(*C*) of the Division of Research Grants, United States Public Health Service, National Institutes of Health. I am indebted to Miss H. van der Noen for assistance.

PATHOLOGY

Vitamin and Coenzyme Content of Hepatomas induced by Butter Yellow

DESPITE the great importance of vitamins and coenzymes to all aspects of metabolism, little attention has been given to the concentration of these compounds in tumours in recent years. In fact, the only systematic study appears to be the work of R. J. Williams and associates[1]. The results of this work demonstrate that the concentration of vitamins in tumours is quite abnormal.

The present investigation was undertaken to study the vitamin and coenzyme contents of one type of tumour in one species. Hepatomas induced by butter yellow (4-dimethylaminoazobenzene) in rats were selected, since they are one of the types of tumour most studied.

Thirty-six male, weanling, albino rats of the Sprague–Dawley strain were fed a 'Purina' diet. After two weeks on this diet, the rats were separately caged and divided into two equal groups. The first group was fed the basal diet as before, while the second was fed the 'Purina' plus 0·06 gm. per cent butter yellow. After 135 days, the animals were killed by decapitation and the livers removed. No tumours were found in the control animals, but of those fed the butter yellow diet 16 of the 18 had large hepatomas. The livers of the control animals, together with the carefully removed hepatomas, were preserved for analysis in the frozen state.

Thiamine assay was conducted with *Saccharomyces cerevisiae*[2], riboflavin assay with *Lactobacillus casei*[3], niacin assay with *Lactobacillus arabinosus*[4], biotin assay with *L. arabinosus*[5], total vitamin B_6 assay with *Saccharomyces carlsbergensis*[6], and pantothenic acid assay with *L. arabinosus*[4] on an enzyme-hydrolysed extract. Vitamin A was detected by the Carr–Price reaction[7], tocopherols by the ferric chloride-α,α-dipyridyl reaction[8] after the removal of interfering substances with concentrated sulphuric acid[9], and ascorbic acid by the 2,4-dinitrophenylhydrazine assay[10].

Diphosphopyridine nucleotide and triphosphopyridine nucleotide were determined by the crystalline alcohol dehydrogenase[11] and *iso*citric dehydrogenase[12] assay methods respectively. The ratio of oxidized to reduced diphosphopyridine nucleotide was determined by the alcohol dehydrogenase method of Holzer *et al.*[13]. Coenzyme *A* was assayed by the arsenolysis method[14].

The results of these determinations are given in Tables 1 and 2.

Table 1. CONCENTRATION OF VITAMINS IN NORMAL LIVERS AND IN HEPATOMAS

Vitamin	Concentration (mean of five determinations, μgm./gm. wet tissue) Normal liver	 Hepatoma
Thiamine	2·8	1·1
Riboflavin	26	4
Niacin	160	33
Biotin	0·85	0·17
Total vitamin B_6	9·0	2·4
Pantothenic acid	91	9
Vitamin A	45·1	8·5
Tocopherols	38	5·1
Ascorbic acid	20	25

Table 2. CONCENTRATION OF COENZYMES IN NORMAL LIVERS AND IN HEPATOMAS

Coenzyme	Normal liver	Hepatomas
Total diphosphopyridine nucleotide (μgm./gm. wet tissue)	480	176
Total triphosphopyridine nucleotide (μgm./gm. wet tissue)	230	24
Diphosphopyridine nucleotide/reduced diphosphopyridine nucleotide	2·2	2·9
Coenzyme A (units/gm. wet tissue)	180	12

It is apparent that the concentrations of many vitamins and coenzymes within hepatomas are very abnormal. Indeed, so different are the concentrations from the normal that they offer an explanation of many of the observed metabolic disturbances of tumours. If tumours have a deranged metabolism because of differences in coenzymes and similar factors, it follows that whatever mechanisms are changing the concentrations must be also the primary causes of tumour incidence. As differences in concentration of vitamins within different cells must primarily depend upon cell permeability, it seems a reasonable hypothesis that the change from a normal to a neoplastic cell may be the result of damage to mechanisms responsible for the transfer of vitamins into a cell.

iliac lymph nodes showed that they contained *C. albicans*. No evidence of *C. albicans* was found in the left external iliac nodes, the liver, the spleen and the lungs.

Two of the guinea pigs inoculated with a suspension of *M. tuberculosis* (strain $H_{37}Rv$) alone died with an infection due to diplococci less than six weeks after injection. After ten weeks, 8 of the remaining 18 guinea pigs died with tuberculous lesions in the liver, spleen and lungs.

When guinea pigs were inoculated with suspensions of *M. tuberculosis* and *C. albicans* the combined infection resulted in a faster evolution of the tuberculous disease. More than 50 per cent of the animals of this group had died within six weeks of inoculation. Necropsy examination disclosed that all these had lesions in the right external iliac lymph nodes and, in many instances, tubercle bacilli were recovered from the internal iliac lymph nodes, from liver, spleen or lungs. By the end of the twelfth week, cultures of the liver, spleen and lungs of two to three times as many of these animals as of the animals inoculated with tubercle bacilli alone showed evidence of growth of *M. tuberculosis*.

In no instance did these animals show any signs of disease of the liver, spleen or lungs that could be attributed to *C. albicans*. *Candida albicans* was recovered from the regional lymph nodes and, in two instances, from small abscesses that had formed at the site of the inoculation in animals that died within the first six weeks. After this time, *C. albicans* was not recovered again by cultural methods from any tissue.

The addition of the polysaccharide fraction to the bacillary inoculum also increased the death-rate of the guinea pigs from tuberculosis within the first weeks of the experiment. The ratio of tissular infection with *M. tuberculosis* was higher than in animals inoculated with tubercle bacilli alone, but inferior to that of animals inoculated with tubercle bacilli and the living yeast cells.

The death-rate of the animals in this experiment and the number of cultures of *M. tuberculosis* obtained from necropsy material are summarized in Tables 1, 2 and 3.

Table 1. DEATH-RATE OF GUINEA PIGS INOCULATED WITH TUBERCLE BACILLI ALONE, WITH TUBERCLE BACILLI AND *C. albicans* CELLS, AND WITH TUBERCLE BACILLI AND THE POLYSACCHARIDES OF *C. albicans* IN THE FIRST WEEKS OF THE EXPERIMENT

Lungs	5/20	12/20	6/20

The results of these experiments show that within the first two months after infection, *C. albicans* increased the invasiveness of the tubercle bacilli. This action can be compared to that of certain extracellular enzymes such as streptokinase or hyaluronidase which are not directly toxic but act as spreading agents for the bacteria which produce them. However, no enzyme that acts on the dissemination of tubercle bacilli *in vivo* has so far been isolated from *C. albicans*. The simultaneous inoculation of 50 mgm. of *C. albicans* polysaccharides reproduced, to a lesser extent, the effect of the living yeast cells by increasing the early death-rate and the dissemination of the tubercle bacilli. The chemical nature of the polysaccharide fraction of *C. albicans* used in this experiment has been studied by Ch. Tanford (personal communication). He pointed out the chemical similarity between this fraction and bacterial 'Dextran UF' described by Greenwood[4,5].

Bacterial dextrans increase the virulence of enterobacteria for rats and mice[6-8]. These dextrans differ in their action from mucin, on one hand, and from the stress-producing substance, adrenocorticotrophic hormone, on the other[9].

The only explanation so far offered for the virulence-enhancing action of dextrans has been proposed by Osalay *et al.*[10], who observed inhibition and destruction of phagocytes in white rats inoculated with dextrans.

The polysaccharide fraction of *C. albicans* represents 10 per cent of the weight of the whole cells[3]. The inoculum of 1 mgm. of yeast cells contained 0·1 mgm. of the polysaccharide fraction. This seems a very small amount of dextrans, unless it is taken into consideration that these cells may have multiplied several times before their ultimate destruction.

RADIOBIOLOGY

Delayed Recovery of Airborne *Serratia marcescens* after Short-Time Exposure to Ultra-violet Irradiation

The phenomenon of the re-activation of bacteria after exposure to ultra-violet irradiation is well known[1-4]. The possibility exists that products formed in the medium by the response of some bacteria, either by death or by adaptation, might have influenced the re-activation of neighbouring bacilli.

During a study of freeze-dried *Serratia marcescens* aerosolized from the dried state[5] a question arose concerning the extent of injury incurred by the airborne bacteria as influenced by the quantity of ultra-violet irradiation. This communication describes a re-activation phenomenon associated with such brief exposures.

In our experiments dried organisms were dispersed into cubic-meter chambers[6] with the enclosed air stirred by a fan. Air samples were collected at intervals by means of a Bourdillion-type slit sampler directly on to blood agar base ('BAB', Difco) medium and the plates were incubated immediately. The viable bacterial concentration/litre of aerosol was then plotted on semi-log paper versus time to determine the overall decay in viability. Because physical loss was small compared to the loss of viability, no adjustment for the former was employed. Ultra-violet irradiation was introduced at the top of the chamber by a Westinghouse Sterilamp No. 7824-10, which was turned on for desired time-periods (20–120 sec.) at 90 min. after aerosol dispersal. A sufficient number of samples was taken before exposure to establish the rate of decay in the absence of irradiation. Each aerosol, therefore, served as its own control.

In the absence of irradiation, the numbers of viable airborne bacteria decreased in an exponential manner. It was expected from this finding that exposure to the lethal radiation would cause a sudden decrease in the numbers of viable cells followed by a continuation of the established rate of decay by those bacilli not influenced by the ultra-violet exposure.

As predicted, there was a sudden loss of viable airborne cells on irradiation. The log of the percentage of survivors correlated with duration of ultra-violet exposure. However, subsequent behaviour was unexpected. After completion of the exposure, and for 15–20 min. thereafter, evidence of an increased rate of decay followed by a short period of recovery was noted. In some cases a second increased rate of decay occurred which continued for about 30 min. followed by a second period of recovery, usually 60–75 min. after exposure. The numbers of viable bacilli then remaining airborne were at a level which would have been expected had no ultra-violet exposure been employed. Fig. 1 is a composite illustration of the behaviour of 30 aerosols tested in this manner. Although not all aerosols exhibited two periods of decay and recovery, all but two indicated that the bacteria recovered to the extent shown by the solid line in Fig. 1. In three instances injury was such that no organisms were recovered from the aerosol during a short time-period after irradiation, though viable micro-organisms were present after additional time had passed. This unusual behaviour was associated with the use of sampling medium which had been dried[7,8] for a longer time than was usually employed to clear excess water from the Petri plates.

Relative Availability of Some Strontium-90 Compounds in Soil

ASSESSMENT of contamination of man's food chain by strontium-90 through plants is complicated by variables in the plant's source of this isotope. Thus the content of strontium-90 in plants from fall-out may be influenced by foliar absorption[1], stem-base absorption[2], and the vertical distribution of strontium-90 in the soil profile[3]. In cultivated soils, the low mobility of strontium-90 coupled with normal tillage practices eventually will lead to a relatively uniform distribution of strontium-90 within the rhizosphere. Consequently the availability of strontium-90 from soil to plants becomes an important factor in hazard evaluation. We believe information regarding availability, and any change with time thereof, can be obtained by successively cropping soil cultures which have been uniformly contaminated with strontium compounds of varying solubility.

Compounds labelled with strontium-90 were prepared (Table 1) and carefully mixed with small aliquots of dry soil previously passed through a 105-mm. mesh sieve. This mixture was blended with more soil in a V-shell blender to yield 500 gm. dry soil (105° C. basis) with a final activity of 0·1 μc./gm. soil. Each chemical form was prepared in triplicate for each of the three soils (Table 1). Random sampling indicated uniform mixing of strontium-90 throughout the soil mass. Beans (*Phaseolus vulgaris* var. Red Kidney) were grown, two plants per pot, in the greenhouse to blossom stage (32 days). Leaves from each pot were combined, wet ashed, and assayed for strontium-90 by conventional counting procedures. Stem data were also obtained, but are not reported since they substantiated leaf results. Strontium-90 content of tissue was used for evaluating relative availability of strontium compounds, thereby avoiding the uncertainties in chemical extraction procedures discussed by Bowen and Dymond[4]. During intervals between crops, the soil was subjected to wetting and drying but was not cultivated. The first fallow period was 32 days and the second was extended to 141 days.

Uptake from relatively insoluble forms was similar and tenfold less than uptake from insoluble forms in

the acidic Cinebar soil. In calcareous soils, the same relationship between soluble and insoluble forms held with the exception of strontium phosphate and carbonate, which were another order of magnitude less available than the soluble forms. The grouping of the response-levels suggested that moderate differences in solubility were not identifiable when compounds were mixed with soil. The sulphate, suggested by Libby[5] as possibly beneficial in soils contaminated by strontium-90, was no less available than other forms the solubility products of which differ by 1 or 2 orders of magnitude. Soil reactions were clearly important in the relative availability of phosphate and carbonate from basic compared to acidic soils. Apatite formation in alkaline soils containing calcite has been shown to include calcium-like atoms in the apatite lattice, thereby removing strontium from solution[6]. We presume this reaction accounted for the reduction of availability of strontium-90 relative to other forms. Such a direct explanation is not apparent for strontium carbonate.

The low availability of strontium phosphate suggested phosphate fertilization as a means of reducing uptake of strontium-90 from contaminated soils. We were able to demonstrate a 50 per cent reduction in uptake of strontium-90 from basic soils treated with massive doses of phosphate[7]. No reduction was observed on acidic soil.

During three croppings there was no major change in availability of soluble or insoluble forms such that a general trend toward equilibrium was indicated. This suggested a prolonged period of equilibration and substantiated observations previously made on strontium-90 aged several years in the field[8]. In these field-studies strontium-90 aged nearly four years was taken up by plants to the same extent as strontium-85 added at the time of testing. In the present test some changes in availability pertaining to certain compounds in one soil were noted. In acidic soil the availability of all strontium salts decreased in the final harvest. This decrease could not be accounted for by depletion of strontium-90 from the soil. In alkaline soils the rate of change was much slower and in the same direction except for strontium carbonate, which became more available with time.

No significant difference existed between the Ephrata and Millville soils with respect to strontium availability although the uptake from these calcareous soils was 2–3 times less than from the acidic soil. The lower uptake from calcareous soils has been largely attributed to the quantities of available calcium. In partial confirmation of the calcium effect, it has been possible to reduce uptake of strontium-90 as much as 80 per cent by additions of lime or gypsum to Cinebar soil, which is low in calcium[9]. Such amendments are without effect on alkaline calcareous soils[10]. In fact, with the exception of the phosphate treatment mentioned, no treatment procedures have been described which depressed strontium-90 uptake from calcareous soils.

The results obtained to date establish the extent to which uptake of strontium-90 might potentially be reduced through precipitation reactions. Further studies are required to determine whether an appreciable part of this potential can be realized. However, initial experiments with phosphate fertilization[7] do not permit much optimism on this point.

This work was performed under Contract No. *AT* (45–1)-1350 between the U.S. Atomic Energy Commission and the General Electric Co.

BIOLOGY

X and *Y* Spermatozoa

A HUMAN spermatozoon contains an *X* or a *Y* chromosome, whereas every human egg contains an *X* chromosome. If, therefore, an *X* spermatozoon fertilizes an egg, the offspring is female; but if a *Y* spermatozoon fertilizes an egg, the offspring is male.

Much effort has, naturally, been expended in trying to separate *X* and *Y* spermatozoa, if only because the separation could be exploited to gratify the wishes of prospective parents. Apart from the

sperm heads. Shettles went on to say that, in one sperm head, three observers independently counted eighteen discrete chromosomes. This is the first time that chromosomes have been 'observed' in a mature sperm head, it having been universally agreed before that discrete chromosomes are not visible in the mature spermatozoon.

Although *X* and *Y* spermatozoa might have been expected to be present in approximately equal numbers, Shettles made no reference to having counted the two types, which is surprising considering the importance of his claim and the ease with which the two types could have been counted.

One photomicrograph, described by Shettles as being of a human sperm head, shows that the head in question is no less than 30μ long, whereas the average human sperm head is 5μ long.

From what has been said, Shettles's claim should clearly not be accepted. The question at issue is: what, in reality, did he observe? Were the round and long black masses distorted vacuoles which occur inside human sperm heads—distorted because of the unusual optical system Shettles used, or because, when dry, human spermatozoa, which are far from being solids of revolution[8], do not always settle on the microscope slide in the same way? Or were the central masses optical artefacts which can easily be demonstrated if crystals in dried human seminal plasma are examined with phase contrast at different focal depths?

To sum up, there is so far no evidence that physical differences have been found between *X* and *Y* spermatozoa.

THE methods of fixation and staining human spermatozoa in the past for bright light and electron microscopy result in alterations and coalescence of the head contents into one mass—a very unnatural state. Consequently, as a result of these changes, the nuclear material of the human spermatozoan head has always appeared very uniform and homogeneous in appearance. It was therefore undesirable to consider the chromatin material in such a state to be normal for the spermatozoan head as it enters the ovum and comes in contact with the egg pronucleus. In his "Developmental Anatomy" (sixth edition, 1954), L. B. Arey states, "The interior of the head contains the tightly packed chromosomes of the sperm cell".

More than a hundred men have now been studied, and the two distinct populations have been repeatedly observed in every semen specimen regarding head and nuclear size and shape, the position, size and shape of the most central chromosomal mass and the pattern of reflected light. The most central mass in each type of head is unequivocally Feulgen-positive, as well

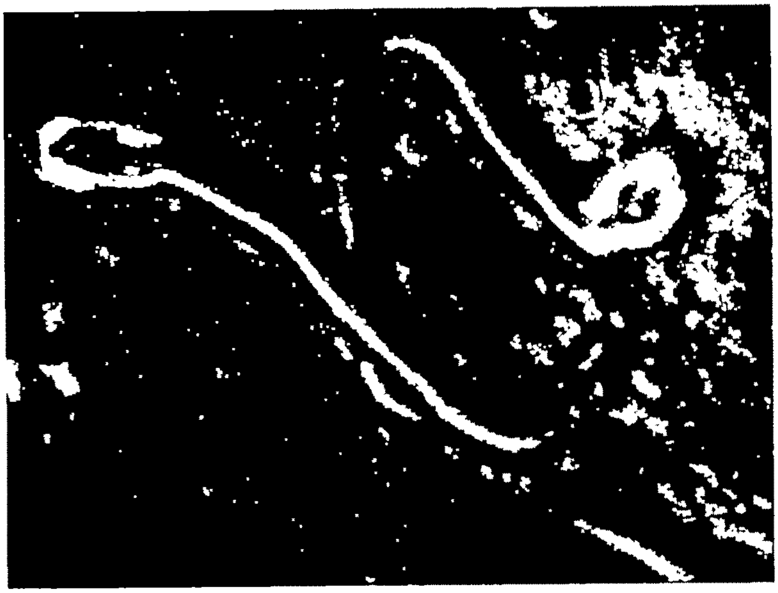

Fig. 1. Living human spermatozoa immobilized in an atmosphere of carbon dioxide Note most central mass in each type of head. Light adjusted to show third dimension. (Original magnification × 1,000. Print provided [by author] has been reduced to ⅔)

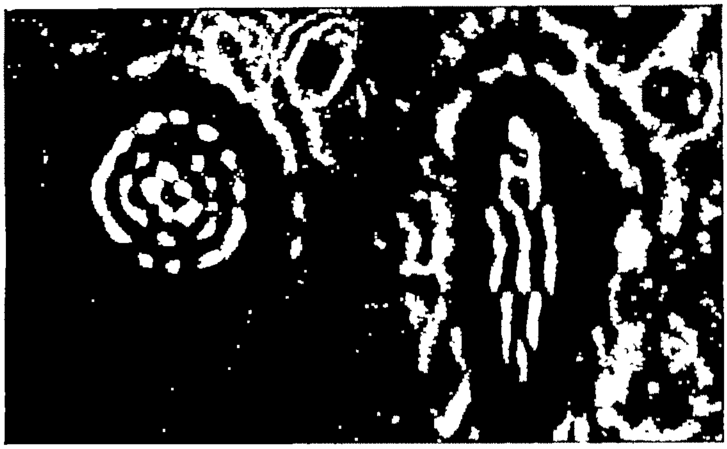

Fig. 2. Dried, unstained human spermatozoon heads showing arrangement of chromosomal material in each type of head. Phase contrast. Heads separated from tails during slight mechanical flattening of heads to facilitate viewing. (Original magnification × 1,000. Print provided [by author] reproduced same size)

as the other compact chromatin masses considered to be the autosomes. Twenty-three chromosomal masses have been counted in some of the rounded type of heads.

The vacuole depicted in the fixed material of the past in bright light and electron microscopic studies can be explained as representing a section taken through the head just beside the most central chromosomal mass (Fig. 1).

Contrary to previous teaching, the ratio of the two types of heads varies from man to man; in most specimens thus far studied, the rounded type predominates. This problem is being studied regarding sex of offspring possibly already produced, frequency of emission and age of individual. Any difference in migratory rates of the two types is also being investigated.

The final enlargement of the illustration referred to by Lord Rothschild and published in my communication of May 21, being enlarged nearly 10,000 times, and its reduction by the printer, do not permit one to figure the original size of the head in microns from the final printing. The length of human spermatozoon heads is often cited to vary from 5 to 8μ; in fact, in some men studied, the larger, normal, elongate types possessed heads 15μ in length.

With a phase-contrast microscope at hand, a semen specimen and glass slides, one can prepare and observe the findings reported in smears directly within just a few minutes. At least 25 different competent observers have been shown preparations; each individual has agreed regarding the two populations.

It has also been found that the two populations can be seen in dried smears viewed in bright light microscopy, with proper adjustment of light intensity. Moreover, the differences in nuclear morphology have been noted in very thin smears of seminal fluid with living spermatozoa immobilized by means of an atmosphere of carbon dioxide (Fig. 1). Furthermore, thin, wet smears observed before, during and after drying under the phase contrast objective of the Zeiss microscope show the two, distinct types of heads. Again, in these the Feulgen test is confirmatory.

There is an exact pattern of arrangement of the Feulgen-positive, concentrically arranged chromosomal material around the most central chromosome in the smaller rounded type of head, and an ovoid pattern in the more elongate type (Fig. 2). Two, most dependable, cytogeneticists have already repeated and confirmed the findings reported regarding the two, distinct populations.

READING Dr. Shettles's first communication[1] leaves one with a variety of disturbing thoughts. Should one be able to hurdle the compounded artefacts of air-dried shrinkage and phase-contrast optical aberration, there still remain the matters of interpretation and communication. Agreeing, but only for the moment, with Dr. Shettles that his Fig. 1 shows "no intermediate types", wherein lies his evidence for specifying the "most central chromosome" either in theory or in Fig. 3? Furthermore, in the light of considerable recent disagreement concerning even the extent and outline of the sperm nucleus, based on cytochemical and electron-micrographic preparations, the description of the ultrastructural pattern of nuclear

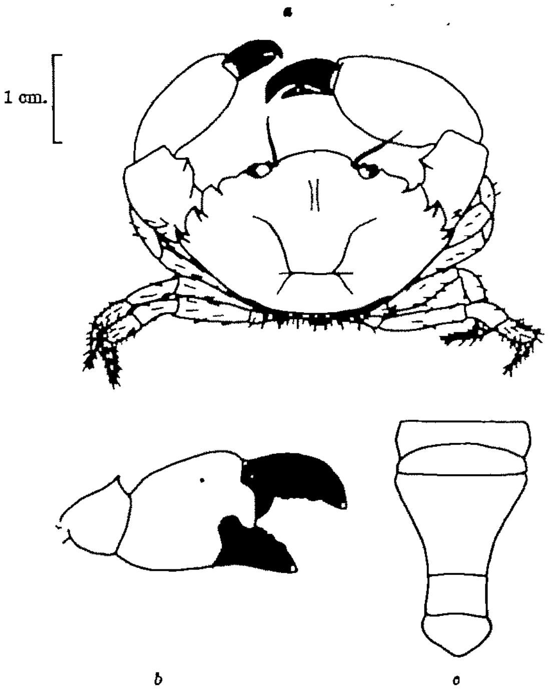

Fig 1. *Neopanope texana sayi* (Smith) ♂: (*a*) dorsal view of whole animal, (*b*) outer view of right chela (enlarged), (*c*) abdomen from below (enlarged)

Inner orbital angle notched. Antero-lateral borders of carapace with five teeth, including outer orbital angle: second rounded and fused with first; third, fourth and fifth sharp and well defined, third and fourth recurved forwards and fifth pointing laterally. Surface smooth except for fine granulations (not pitted). *Chelæ* (Fig. 1*a* and *b*) slightly unequal in size, inflated and smooth. *Walking legs* (Fig. 1*a*) all subequal in length; distal parts, particularly propus and dactylus, fairly densely fringed with fine setæ. Legs and bases of chelæ scattered with longer, plumose setæ which often appear club-shaped owing to the adherence of detritus. *Abdomen* of male (Fig. 1*c*) with segments 3, 4 and 5 fused; narrowest between fused segments and segment 6; segment 7 triangular. Abdomen of female broadly rounded and very densely fringed with setæ. *Colour* of dorsal surfaces reddish-brown. Ventral surfaces yellow. Fingers of chelæ dark brown. Males with the deeply pigmented area of the fixed finger having its border extended postero-dorsally in a lobe on each side (Fig. 1*b*); pigmented area less extensive in the female and posterior border not lobed. Extreme tips of chelæ lighter in colour. *Size*: the breadth × length measurements (mm.) of the carapace of ten specimens were as follows: males, 30 × 21, 30 × 21, 29 × 21, 29 × 20, 26 × 19, 26 × 18·5, 24 × 17, 23 × 16, 17 × 13; female, 21 × 16.

Neopanope texana sayi differs in several respects from *N. t. texana*, a closely related form, which has, in particular, light-coloured fingers on the chelæ and has sharper and more extensively produced lateral teeth on the carapace[1]. *N. t. texana* is a more subtropical form which is found in the Florida Keys and in the Gulf of Mexico[1]. In Britain the immigrant *Neopanope* shows superficial similarities with native species of *Xantho* but it may be distinguished from the latter genus on several points[7]. In *Neopanope* the carapace is more convex than in *Xantho*, while the surfaces of the carapace and chelæ are smooth and not pitted. They are pitted in the British forms *Xantho incisus* Leach and *X. pilipes* Milne Edwards. In *Xantho*, moreover, the second lateral tooth on the carapace is relatively more distinct than in *Neopanope* and teeth 3 and 4 are not recurved forwards.

I am grateful to Dr. Isabella Gordon and Mr. R. Ingle for their help at the British Museum (Natural History). Mr. W. A. C. Morris kindly provided information about shipping which operates between North America and Swansea.

Earthworm Population Studies: a Comparison of Sampling Methods

SVENDSEN[1] showed that the estimate of an earthworm population obtained by hand sorting soil samples was much greater than that by the prevalent method of bringing worms to the soil surface with potassium permanganate solution, and so emphasized that, although laborious, hand sorting was more accurate for population studies. The accuracy of estimates by hand sorting has not been studied but is likely to depend on soil type and conditions, as well as on the time and care taken to examine the sample. One way to estimate accuracy is to see how many worms can be recovered when samples, already hand sorted, are examined again by a different method.

While investigating the role of earthworms when marginal land is reclaimed, their abundance had to be estimated in experimental plots on a hill farm in Lancashire where the soil is relatively shallow, has a poor, unstable structure, and is covered by a surface mat of vegetation. This mat and the underlying soil were usually wet and often waterlogged, and preliminary work showed that the earthworms were confined to the top few inches of the soil profile. Soil samples were taken for hand sorting, and, to estimate the proportion of the population counted in this way, 9 of the sorted samples, 3 from each of 3 experienced workers, were examined again in the following way.

The vegetation was separated from the mineral fraction by gently washing and shaking the sample in a 2-mm. sieve suspended within a 0·5-mm. sieve standing in a bowl of water. Worms were then collected from the vegetation by teasing it in another bowl of water containing a few c.c. of formalin to make the worms wriggle and so be more obvious. After the mineral fraction was washed through the 2-mm. sieve into the 0·5-mm. sieve, so freeing any worms from soil crumbs, this sieve was shaken in the water for a time to allow silt to pass through it. It was then immersed in magnesium sulphate solution, of density 1·2, when the worms floated and were collected.

Table 1 shows that hand sorting recovered 52 per cent of all the worms found in the samples. This corresponded to 84 per cent of the weight, which shows that hand sorting mainly misses the smaller worms. How this selective loss can affect population estimates is well shown by the results for a small species such as *Eiseniella tetraedra*. Hand sorting recovered only 38 per cent of the total number and 57 per cent of the total weight of this species found in the samples and suggested that it comprised 49 per cent of the total number and 18 per cent of the total weight of all species. When the worms recovered by washing are included, *E. tetraedra* comprised 68 per cent of the total number and 26 per cent of the total weight of the population. Clearly hand sorting was unsatisfactory for this habitat, and the washing method, though no more laborious, was preferable.

Table 1. RECOVERY OF EARTHWORMS FROM NINE SOIL SAMPLES BY HAND SORTING AND WASHING

		Worms found by hand sorting	Additional worms found by washing	Total found	Percentage found by hand sorting
All species	Number	256	236	492	52
	Weight (gm.)	13·47	2·55	16·02	84
Eiseniella tetraedra	Number	125	208	333	38
	Weight (gm.)	2·38	1·81	4·19	57

In similar tests with soil samples from grassland with no surface mat on a light, well-drained soil at Wisbech, and from a heavier, well-drained soil at Rothamsted, 89 per cent of the total number and 95 per cent of the total weight found was recovered by hand sorting, which was also much quicker than washing. In contrast, hand sorting samples from an old arable field with heavy soil and poor structure recovered only 59 per cent of the total number and 90 per cent of the total weight found and was no quicker than washing.

The washing method not only provides a check on the efficiency of hand sorting, but, for some habitats, also provides a much more accurate estimate of the earthworm population. The washing method has the further advantage that it can be adapted to extract earthworm egg capsules and so estimate all stages of the population.

Modification of the Neurocranium in *Zygaena malleus* and the Nature of the Optic Stalk in Selachii

GENERALLY in Selachii, between the nasal and auditory capsules, on each side, are the orbits in which the eyes are lodged. The orbit is overhung by the supraorbital cartilage which extends anteriorly and posteriorly to the orbit as the pre- and post-orbital processes respectively. The optic capsule, which is represented by the sclerotic cartilage, does not fuse with the brain-case, as the nasal and auditory capsules do; but it is held away from the orbital wall by the cartilaginous optic stalk, which is proximally fused with the orbital wall.

In *Zygaena malleus* only the most anterior and most posterior parts of the supraorbital cartilage are represented, forming the pre- and post-orbital processes. The orbit (Fig. 1, *Or.*) has retained a secondary

Plant Hormone Activity: Stilbœstrol applied to the Wheat Seedling

THE presence in plants of substances having œstrogenic activity has been known for some time, œstrone, œstriol and œstrogenic *iso*-flavones having been isolated from a number of plants[1]. Many plant hormones are also known to exhibit hypo-glycæmic activity in animals. On the other hand, this may be the result of inhibition of insulinase and not a hormonal effect, although the auxin and insulinase-inhibiting activities of a number of indole-acids, chloro-phenoxyacetic and chloro-benzoic acids run parallel[2]. There is also evidence to show that the sex of flowers of the normally diœcious *Melandrium dioicum* can be partially influenced by mammalian œstrogenic and androgenic hormones[3].

This communication reports, as a further example of the complementary reaction of plants to substances with hormonal activity in animals, the 'hormonal' activity of synthetic œstrogens on the roots of the wheat seedling.

Fig. 1 shows the tropic response of the roots of wheat grains germinated on the surface of an agar water gel containing 50 p.p.m. of stilbœstrol. This response followed when the roots approached the surface at an angle; those which touched it in a near vertical position grew into the gel, though at a rate only about a twentieth that of roots growing into pure agar gel. A vigorous and certain response was also only obtained when the gel was freshly prepared, probably because this concentration of stilbœstrol is about three times its true solubility at room temperature and its strength gradually falls as crystallization takes place.

An alternative method of demonstrating the effect was to germinate the grain in water until the roots

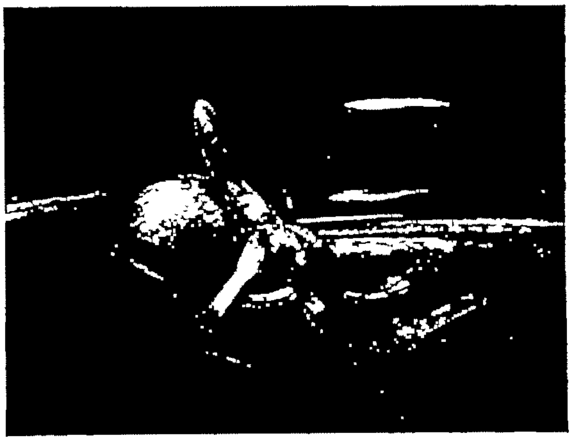

Fig. 1. Curvature of roots of germinating wheat induced by stilbœstrol

were a few millimetres long, when it was transferred to a block of pure agar gel placed in a Petri dish. By placing the grain so that 1–2 mm. only of the root tip overhung the edge of the agar and keeping the dish covered, the roots were kept sufficiently moist to maintain growth. Stilbœstrol was applied as a minute crystal to one side of the tip. Curvature of the root was first noticeable after approximately 2 hr., the curvature indicating increased growth on the side to which stilbœstrol had been applied. Curvature also occurred in other tests, following the application of stilbœstrol, when the root was in a vertical position. When stilbœstrol was applied mixed with lanolin or 'Vaseline', in the manner used successfully in the testing of auxin activity, no response was obtained. The appearance suggested that the greasy base failed to adhere to the moist root surface.

Using this method of direct application to the root, an attempt was made to distinguish the sensitive region. Curvature occurred in the region of extension growth a little way behind the tip, but application of stilbœstrol at this point was not effective. The sensitive region was found to be approximately the root-cap, and application outside this area had no effect.

The coleoptile appeared to be insensitive to stilbœstrol when this was applied in agar as in Went's coleoptile test[4], or as a minute crystal applied to one side of its surface, either unbroken or abraded or at the surface of a cut made completely through the tissue. The application was made at various regions near the tip and at different stages in the growth of the coleoptile. Tests were made on grains held in the dark and in the light, but no curvature was obtained in any of these experiments.

Activity of Allied Substances. E. C. Dodds and his co-workers found œstrogenic activity in other compounds possessing the basic di-phenyl structure of stilbœstrol[5]. Five of these compounds and three natural steroids have been tested.

Diphenylethane and stilbene had no activity. 4-4 Dihydroxydiphenyl induced a slight curvature, but 2-2 dihydroxydiphenyl was inactive. No activity was shown by œstrone, œstradiol, œstradiol benzoate and testosterone.

Phenol in agar in a range of concentration from 0·1 to 400 p.p.m. produced no curvature, but at 400 p.p.m. it inhibited growth. When applied direct to the root, the two dihydroxydiphenyls damaged the tissues at the point of application and the meristem afterwards died. Dilution by thorough mixing with five to ten parts of an inert substance was necessary to prevent harmful effects. In these experiments wheaten flour was used as the diluent.

When hexœstrol was applied direct to the root, curvature followed as with stilbœstrol. Less-certain and sometimes feeble results were obtained, however, from a solution in agar. This was probably the result of its lower solubility in water as compared with stilbœstrol. Approximate figures for the solubilities were measured, using a *p*-nitroaniline reagent[6] and comparing the colour developed with a standard curve prepared with warm solution. They were 7 and 15 p.p.m. respectively.

Interpretation of the results is complicated by the different solubilities in water of the materials tested. In general, it is probable that the natural steroids, which were ineffective, are less soluble than the synthetic œstrogens, and this will affect their rate of movement into and within the root. The same consideration applies to diphenylethane and stilbene, both of which were found by Dodds to possess activity. They had no activity when applied to the root, but the more soluble 4-4 dihydroxydiphenyl, which also possesses œstrogenic activity, produced slight curvature. By evaporating solutions saturated at room temperature and weighing the residue, the solubilities of stilbene and 4-4 dihydroxydiphenyl were found to be of the order of 10 and 70 p.p.m. respectively. The damage to the root tissue following the direct application of the dihydroxydiphenyls, which was not observed with any of the other substances, may also be due in part to their greater solubility.

Stilbœstrol was completely ineffective in producing curvature in the coleoptile under the conditions tested, which include those usually employed to demonstrate and measure the auxin stimulus on cell extension. This leaves its mode of action unexplained. A stimulating effect of stilbœstrol, œstrone and œstradiol on cell division in mouse ear epidermis held in tissue culture has been reported[7]. Such an effect, if it can be demonstrated in roots, would provide an explanation of our observations, but it is apparently contradicted by the considerable check in growth of those roots which actually grew into the gel containing stilbœstrol.

Our thanks are due to Sir Charles Dodds and Prof. L. J. Audus for their advice in the preparation of this communication.

Relative Lengths of Leaf Sheath and Blade with Reference to the Developmental Stages of the Rice Plant

DIFFERENT vegetative characters are taken into consideration for describing the individual groups and varieties of rice (*Oryza sativa* L.), but little importance has so far been attached to the behaviour of the plants with regard to the ratio of the length of leaf sheath to that of leaf blade. With the view of studying the sequences of the ratios in all the successive mature leaves and their relationship with certain important developmental stages, the present investigation was undertaken with three rice varieties, namely, *F.R.*13*A* (aman). *Satika* (aus) and *C.B.*1 (boro).

Seeds of the three varieties were directly sown in pots on June 10, 1959. The lengths of leaf sheath and blade were measured periodically, and this recording was continued up to the harvesting time. The individual length of the leaf sheaths and leaf blades as indicated in the graphs (Figs. 1 and 2) represented an average of about 21 measurements.

The number of leaves on the main culm was recorded to be 18, 11 and 14 in *F.R.*13*A*, *Satika* and *C.B.*1 respectively; their hard culm bases were

d in respectively *F.R.*13*A*,

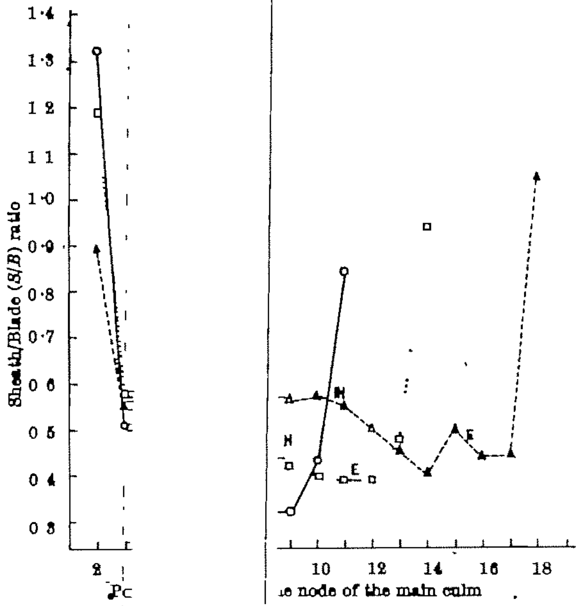

Fig. 2. She… ath/blade ratios in the successive mature leave… Satika (○) and C.B 1 (□). E and *IN* indicate… of ear initiation and that of inter-elongation

The sheaths in almost all the three varieties continued to increase in length until the beginning of internode elongation. The length of leaf blades, however, showed a gradual rise from the second to the eighth in *Satika* and to the eleventh in *C.B.*1. In both of them with the formation of long internodes the length of the leaf blade recorded an abrupt jump and continued to rise until a fall was noted in the last three leaves (Fig. 1).

The sheath/blade ratio of the second leaf was usually more than unity in *Satika* and *C.B.*1 and slightly less in *F.R.*13*A*. In most of the later-formed leaves, the ratios were, however, far less than unity. In *Satika* and *C.B.*1 the sheath/blade ratios increased distinctly from the fourth leaf onwards up to the leaf developing before the formation of long internodes, but with the initiation of internode elongation they showed a definite and gradual fall up to the eighth and eleventh leaf respectively, that is, the fourth leaf from the terminal ear leaf (Fig. 2).

The ratios in the tenth leaf of *Satika* and thirteenth leaf of *C.B.*1 (that is, the second from the terminal one) showed a sharp rise from those of the leaves developing in the culm elongation phase, when the ear primordium was noted to have already developed fairly distinctly. In the ear leaf of *Satika* and *C.B.*1, the ratio was slightly less than unity, which was more in *F.R.*13*A*. The variation in leaf size developing during the ear formation may result from the great consumption of energy and a drop in carbon/nitrogen ratio as indicated by Nagai[2]. Although ear formation becomes apparent from the ear leaf having a blade relatively shorter and broader, this indication could also be noted even much earlier from the size variation of the leaf developing just before the ear leaf.

The culm elongation phase has been noted to be accompanied by a definite fall in sheath/blade ratios, when the main culm forms more than half the total number of leaves in *F.R.*13*A*, *Satika* and *C.B.*1. Ear formation is evident much earlier from the higher sheath/blade ratio of the leaf, second from the terminal leaf.

I am grateful to Dr. B. C. Kundu, director of this Institute, for the facilities to carry out the work and also to the National Institute of Sciences of India for the award of a Senior Research Fellowship.

SOIL SCIENCE

Ammonia released on Treating Soils with *N* Sodium Hydroxide as a Possible Means of predicting the Nitrogen-supplying Power of Soils

THE only reliable method at present available for estimating the potential nitrogen-supplying power to crops of the organic nitrogenous fraction of soils is the incubation procedure. In this, soils are incubated under optimum conditions of moisture and temperature for periods of two weeks or longer and the quantity of nitrogen mineralized taken as a measure of their nitrogen-supplying power. Many workers have shown good correlations between the amount of nitrogen mineralized during incubation and crop production. These results have been well summarized by Harmsen and van Schreven[1]. The main drawbacks of the incubation method are the length of time required and the relative tediousness involved in extracting and determining mineralized nitrogen. A quicker method which also requires less manipulation is obviously desirable, particularly where large numbers of samples are being tested, such as in advisory work.

In some studies being carried out with the view of determining whether any single fraction of the soil organic nitrogen contributed to the nitrogen mineralized during incubation, it was noted for a number of soils that the amount of ammonia released on treating them with *N* sodium hydroxide was positively correlated with the amount of nitrogen mineralized during incubation of the soils. In order to see if this relationship held for a large variety of cultivated soils the two methods were tested on 48 garden and allotment soils ranging in texture from sands to clays, with total nitrogen of 0·01–0·35 per cent, and *p*H of 4·7–8·2, and including 13 soils containing free chalk. The soils were sampled during November and December after digging and subjected to the two procedures within two weeks of being air-dried. After rubbing the soils through a 2-mm. sieve, the incubation test was carried out as previously described[2] (3 weeks incubation at 28° C. with moisture content adjusted to 33 per cent of the maximum water-holding capacity of the soils) and mineral nitrogen was extracted with *N* sodium chloride and determined by the Bremner–Shaw modification[3] of the Conway microdiffusion method. The air-dried soils were also analysed for extractable mineral nitrogen in the same way, the differences between the two results giving the amounts of nitrogen mineralized during incubation. The 'Perspex' cells used in the Bremner–Shaw method were also found to be very satisfactory for determining the release of ammonia on treating the soils with alkali. After preliminary studies on the effect of varying the soil : alkali ratio, degree of agitation and time, the following procedure was adopted: 2 gm. air-dried 2-mm.-sieved soils and 5 ml. *N* sodium hydroxide were placed in the outer ring of the cell without mixing, and 2 ml. 2 per cent boric acid was placed in the central chamber. After sealing the lid with the gum acacia fixative the cell was rotated gently for about 30 sec. to mix the contents of the outer ring, allowed to stand for about 1 hr., agitated again for about 30 sec. and then placed in an incubator at 28° for 40–42 hr. The ammonia absorbed by the boric acid was determined by titration with standard acid using a methyl-red–methylene blue indicator[4].

Fig. 1 shows the relationship between results obtained by the two methods. In the diagram the soils are indicated in three groups, namely, calcareous soils, those with $pH > 6$ and those with $pH < 6$. The linear correlation coefficient is 0·845 and is very highly significant. The pattern of the relationship appears to be independent of soil *p*H and the presence of free chalk. Most of the acid soils give relatively low values, while most of the chalky soils give high values, for both determinations. The amount of ammonia released on treating the soils with *N* sodium hydroxide averaged four times that mineralized during incubation, and accounted for an average of 8 per cent of the total nitrogen present in the soils. The action of the alkali presumably results in the hydrolysis of a certain amount of the organic nitrogenous materials present, resulting in the release of ammonia from the amide linkages of proteins and possibly also from other sources[5].

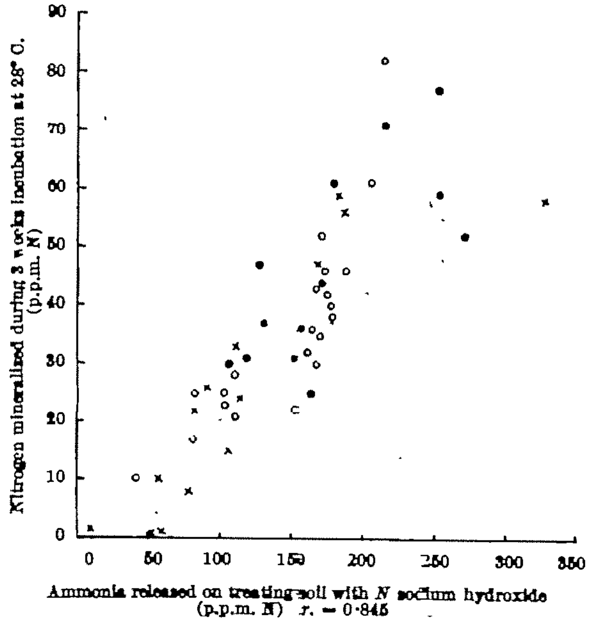

Fig. 1. Relationship between nitrogen mineralized in soils during 3 weeks incubation and ammonia released on treating soils with *N* sodium hydroxide. Linear correlation coefficient = 0·845. ●, Calcareous soils; ○, soils with $pH > 6$; ×, soils with $pH < 6$

In spite of the high correlation between the results obtained by the two methods, individual variations are fairly high. Hence only an approximate prediction of nitrogen mineralized during incubation can be obtained from a knowledge of the amount of ammonia released on treating the soil with *N* sodium hydroxide. However, the method may be useful for advisory purposes and also for screening soils before applying the more tedious incubation procedure.

Aluminium Interlayers in Clay Minerals, Montmorillonite and Vermiculite: Laboratory Synthesis

Aluminium interlayers in pure montmorillonite and vermiculite have been produced experimentally as proposed in an earlier communication[1]. These aluminium interlayers resulted in a stable 14-Å. spacing and a reduced cation exchange capacity analogous to the stable spacing[2–4] and reduced exchange capacity[4] encountered in 'chloritized'[1] soil clays.

The interlayers were experimentally introduced under conditions resembling those where interlayers are naturally found: abundant aluminium ions and

chloride solution, and then raising the pH of the suspension to 5 and setting the suspension aside for fifteen days.

The introduction of aluminium interlayers in both montmorillonite and vermiculite caused a striking decrease in the cation exchange capacity of these minerals as determined by the method of Sawhney *et al.*[5]. Introduction of the interlayers decreased the exchange capacity 45 and 53 per cent in the vermiculite and 23 and 30 per cent in the montmorillonite (Table 1). The laboratory introduction of aluminium interlayers into montmorillonite and vermiculite thus produced clays that resembled the chloritized soil clays[4] in their reduced exchange capacity.

When chloritized soil clays were extracted with citrate[2] for the removal of aluminium interlayers, their exchange capacity increased and their 14-Å. spacing collapsed to 10 Å. on saturation with potassium[4]. Also, when the samples with aluminium interlayer produced in the laboratory were extracted with citrate, the 14-Å. spacing collapsed to 10 Å. on potassium saturation, and the exchange capacity increased to that of the original minerals.

The laboratory formation of aluminium interlayers in expanding layer silicates, and the similar behaviour of the laboratory products and the natural soil clays lend further support to the hypothesis that 'chloritization' of soil montmorillonite and vermiculite gives rise to the stable 14-Å. spacing, which has characteristics tending towards those of chlorite. The different degrees of chloritization in soil clays is shown by the varying stability of the 14-Å. spacing, and also by the varying increase in exchange capacity elicited by the removal of aluminium interlayers[4]. The aluminium interlayers are probably comprised of the polymers[6] of $Al(OH)_2^+$ ions, which are most abundant at pH 5.

Aluminium interlayer formation or 'chloritization' in expanding layer silicates in soils is analogous to diagenesis of chlorite in sediments[7]. The cationic environment of sediments produces brucitic interlayers as contrasted to the gibbsitic interlayers observed in soil clays. The chloritization process in both sediments and soils produces a 14-Å. spacing, more stable than that of vermiculite but less stable than that of hydrothermal chlorite.

FORTHCOMING EVENTS

Monday, July 18—Friday, July 22

THE NATIONAL FOUNDATION (U.S.A.) (at Church House, Westminster, London, S.W.1), at 9.30 a.m. daily—First International Conference on "Congenital Malformations".

Tuesday, July 19

PLASTICS INSTITUTE (at the British Plastics Federation, 47/48 Piccadilly, London, W.1), at 2.15 p.m.—Annual General Meeting.

Wednesday, July 20

ROYAL SOCIETY (at the Royal Institution, 21 Albemarle Street, London, W.1), at 10.15 a.m.—Prof. C. D. Darlington, F.R.S.: "The Chromosomes and the Theory of Heredity". 2.30 p.m.—Sir Alexander Todd, F.R.S.: "New Horizons in Organic Chemistry" (Tercentenary Lectures).

ROYAL SOCIETY (at the Beveridge Hall, University of London, London, W.C.1), at 10.15 a.m.—Sir Christopher Hinton, K.B.E., F.R.S.: "The Evolution of Nuclear Power Plant Design". 2.30 p.m.—Prof. C. F. Powell, F.R.S.: "The Study of Nuclear Disintegrations produced by Particles of Energy" (Tercentenary Lectures).

ROYAL SOCIETY (at The Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2), at 10.15 a.m.—Prof. P. B. Medawar, C.B.E., F.R.S.: "The Problems of Transplantation". 2.30 p.m.—Prof. A. L. Hodgkin, F.R.S.: "The Physics and Chemistry of Nervous Conduction" (Tercentenary Lectures).

Thursday, July 21—Wednesday, July 27

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS AND COMMUNICATIONS SECTION (in association with the INTERNATIONAL FEDERATION FOR MEDICAL ELECTRONICS, at Olympia, London, W.14)—Third International Conference on "Medical Electronics".

Saturday, July 23

ROYAL SOCIETY (at the Beveridge Hall, University of London, London, W.C.1), at 10.15 a.m.—Dr. Dorothy Hodgkin, F.R.S.: "Molecules in Crystals" (Tercentenary Lecture).

ROYAL SOCIETY (at the Royal Institution, 21 Albemarle Street, London, W.1), at 10.15 a.m.—Prof. A. C. B. Lovell, O.B.E., F.R.S.: "The Investigation of the Universe by Radio Astronomy" (Tercentenary Lecture).

ROYAL SOCIETY (at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2), at 10.15 a.m.—Prof. V. B. Wigglesworth, C.B.E., F.R.S.: "The Metamorphosis of Insects" (Tercentenary Lecture).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURER (man or woman) IN CHEMISTRY—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey (July 20).

LABORATORY HISTOLOGICAL TECHNICIAN, to train and work in electron microscopy—The Secretary, Institute of Neurology, National Hospital, Queen Square, London, W.C.1 (July 20).

SENIOR LECTURER IN PHYSICAL CHEMISTRY; and a LECTURER IN ELECTRICAL ENGINEERING (ELECTRONICS)—The Registrar, Lanchester College of Technology, Priory Street, Coventry (July 20).

FEMALE RESEARCH ASSISTANT (preferably with experience of survey work, interviewing and typing), for social work in a programme of human genetical research—The Secretary, Department of Biology as Applied to Medicine, Middlesex Hospital Medical School, London, W.1 (July 22).

LECTURER IN ORGANIC CHEMISTRY at the University of New England, Armidale, N.S.W., Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, July 22).

LECTURER IN PHYSICS—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (July 22).

GRADUATE IN BIOLOGY (male or female, with experience of routine laboratory techniques, in particular biological assay), to work in Central London on testing spermicidal products and to undertake research into methods of fertility control—Mrs. R. Peers, International Planned Parenthood Federation Medical Committee, 19 Clarendon Road, London, W.11 (July 23).

LECTURER IN PHYSICS, and a LECTURER (graduate in pharmacy or physiology, with experience or specialization in pharmacology) IN PHARMACOLOGY—The Bursar, College of Advanced Technology, Gosta Green, Birmingham 4, quoting "D" (July 23).

RESEARCH STUDENTS (2) (graduates in chemistry, biochemistry or physiology) IN THE CANCER RESEARCH DEPARTMENT, for work on the biochemical and immunological aspects of carcinogenesis—The Registrar, The University, Nottingham (July 23).

ASSISTANT LECTURER IN PSYCHOLOGY—The Registrar, The University, Hull (July 25).

RESEARCH ASSISTANT (with a physics degree and a good knowledge of electronics) IN THE GEOPHYSICS SECTION OF THE GEOLOGY DEPARTMENT—The Professor of Geophysics, Imperial College of Science and Technology, London, S.W.7 (July 25).

SENIOR LECTURER or LECTURER (male, British, with a first- or second-class honours degree in physical metallurgy or equivalent, and preferably some teaching experience) IN THE CHEMISTRY AND METALLURGY DEPARTMENT, R.N. College, Greenwich, London, S.E.10—The Director (P/3), Naval Education Service, Admiralty, London, S.W.1 (July 25).

TEMPORARY ASSISTANT LECTURER IN PHILOSOPHY or an ASSISTANT LECTURER IN PHILOSOPHY—The Registrar, University College of North Staffordshire, Keele, Staffs (July 29).

ASSISTANT LECTURER IN THE DEPARTMENT OF METALLURGY—The Registrar, The University, Manchester 13 (July 30).

JUNIOR LECTURER IN BIOCHEMISTRY—The Secretary, Medical College of St. Bartholomew's Hospital, West Smithfield, London, E.C.1 (July 30).

LECTURER (medical or dental graduate) IN DENTAL BACTERIOLOGY—The Secretary, The University, Edinburgh (July 30).

LECTURER or ASSISTANT LECTURER IN MATHEMATICS—The Secretary, Royal College of Science and Technology, Glasgow (July 30).

LECTURER (preferably with experience in teaching biochemistry to medical and science students) IN BIOCHEMISTRY—The Secretary, Medical College of St. Bartholomew's Hospital, West Smithfield, London, E.C.1 (July 30).

LECTURER IN BACTERIOLOGY at the Western Infirmary—The Secretary of University Court, The University, Glasgow (August 1).

PEDOLOGIST AND SOIL SURVEYOR (honours graduate in science or agricultural science with some years research experience, preferably in soils investigations) at the Regional Centre, Commonwealth Scientific and Industrial Research Organization, Brisbane, Queensland, to carry out soil surveys and pedological investigations in a variety of regions to assist in the numerous aspects of land development and irrigation, to facilitate soil fertility studies and to establish fundamental pedological principles of use in the development and application of soil sciences—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 270/237 (August 6).

SENIOR BACTERIOLOGIST, SENIOR CONSULTANT (with a degree in human or veterinary medicine or microbiology with Ph.D. or equivalent) IN THE NATIONAL BIOLOGICAL STANDARDS LABORATORIES, Canberra, for the supervision and recruitment of staff to assay the potency, purity and safety of human and veterinary bacterial and therapeutic agents—The Director-General of Health, Department of Health, Canberra, Australia (August 6).

ANALYST (with a degree in chemistry or biochemistry, or considerable experience in analytical chemistry) IN THE DEPARTMENT OF CHEMICAL PATHOLOGY—The Registrar, The University, Leeds 2 (August 8).

LECTURER IN PSYCHOLOGICAL MEDICINE—The Secretary of University Court, The University, Glasgow (August 13).

ASSISTANT LECTURER (with a veterinary or medical qualification or a degree in zoology) IN HISTOLOGY AND EMBRYOLOGY—The Secretary, Royal Veterinary College (University of London), Royal College Street, London, N.W.1 (August 15).

LECTURER IN GEOGRAPHY at Rhodes University, Port Elizabeth, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, August 15).

LECTURER (with a good honours degree in physics or equivalent and preferably teaching experience) IN THEORETICAL PHYSICS at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, August 15).

LECTURERS IN PHYSICAL AND IN ORGANIC CHEMISTRY at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, August 15).

ANALYST, Assistant Experiment Officer grade, for experiments on sugar beet, at first near Lincoln and later near Bury St. Edmunds—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (August 20).

ASSISTANT EXPERIMENTAL OFFICER or EXPERIMENTAL OFFICER (graduate in a biological science or agriculture, for experiments on sugar beet, first at Dunholme Field Station, near Lincoln, and later near Bury St. Edmunds—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (August 20).

CHAIR OF THEORETICAL PHYSICS in the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, August 31).

LECTURER IN ARCHAEOLOGY—The Secretary of University Court, The University, Glasgow (August 31).

PRINCIPAL (with high academic qualifications and appropriate educational and administrative experience) OF THE NORTHERN POLYTECHNIC—R. H. Currell, F.C.A., Clerk, Northern Polytechnic, London, N.7 (October 15).

ASSISTANT BIOCHEMIST, Basic grade (with an appropriate science degree or Associateship or Graduate Membership of the Royal Institute of Chemistry) IN THE DEPARTMENT OF PATHOLOGY—The Superintendent, Northampton General Hospital.

ASSISTANT LECTURER (Grade B) IN ORGANIC CHEMISTRY—The Registrar, Hatfield Technical College, Hatfield, Herts.

ASSISTANT LECTURER, Grade B (with an honours degree in physics and research or industrial experience in some branch of applied physics) IN THE DEPARTMENT OF PHYSICS—The Registrar, College of Science and Technology, Ashley Down, Bristol 7.

BIOCHEMIST (Senior or Basic grade) to the Rochdale Group of Hospitals, to work under the Consultant Pathologist and to carry out biochemical work for the hospitals and clinics of the group—The Group Secretary, Rochdale and District Hospital Management Committee, Birch Hill Hospital, Rochdale, Lancs.

BIOLOGIST, to carry out research on certain aspects of *Tilapia* fish culture in East Africa—work to be based at the East African Fishery Research Organization at Jinja in Uganda and the Inland Fishery Research Station at Sagana in Kenya—The Director, Nuffield Foundation, Nuffield Lodge, Regent's Park, London, N.W.1.

BIOMETRICIAN, Scientific Officer or Senior Scientific Officer (graduate in mathematics with an interest in biology) IN THE SECTION OF STATISTICS—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 60/10.

THE ROYAL SOCIETY

"THE Royal Society of London for Improving Natural Knowledge", as the Society is described in its second charter of 1663, is celebrating the three hundredth anniversary of its foundation, and the presidential address by Sir Cyril Hinshelwood is printed in this issue (p. 274). Thus the Society is one of the oldest learned institutions in the world and is unique in its unbroken record of activity. During the years, its influence has varied in response to the circumstances of history, but it is worth emphasizing that even during periods of great national stress, such as the Napoleonic Wars, its Fellows were able to continue their investigations and even to correspond actively with, and to meet, scientific colleagues in other countries.

From its beginnings with private meetings in Oxford and London, the Royal Society has advanced, under a succession of distinguished presidents and officers, keeping in touch with current affairs, and steadily establishing the world-wide prestige in which it is now held. This curious combination of respect for the past and its gracious ways—the Society's present meeting room with the out-moded arrangement of the officers' seats is a case in point—with lively concern for modern topics, such as space research, is perhaps typical. The Society provides an outstanding example of adaptation or evolution in the conduct of human affairs.

It is not always realized how wide is the range of activity of the Royal Society in modern times. Thus it not only provides a forum for the discussion and publication of scientific papers, but also undertakes a number of public responsibilities. It is the 'adhering organization' for the United Kingdom with regard to the International Council of Scientific Unions and appoints delegates for meetings of the Council and of the several component Unions. This is done through national committees for the several subjects represented by the International Unions. On behalf of the Committee of the Privy Council for Scientific and Industrial Research, the Royal Society is responsible for the management of the scientific work of the National Physical Laboratory. It also takes an important part in the management of the affairs of the Royal Greenwich Observatory, and it is the custodian of one of the four copies of the Imperial standard yard and pound. The Society also appoints or nominates representatives to the governing bodies of the British Museum, the Spectator Committee, the Times Holding Company, and many scientific bodies, research institutions, schools, etc. In this way the Society is enabled to keep in touch with the changing scene, and also to give advice and counsel. A number of trust funds providing for research appointments are also administered by the Society. In addition, it is responsible for Parliamentary grants-in-aid for scientific investigations, for scientific publications and for international research associations and scientific congresses; these grants, some of which began in the 'fifties of the last century, have grown to substantial sums, and their use has proved to be of considerable importance, for example, for the publication of scientific papers, etc., not by the Royal Society alone, but through other channels. Incidentally, it may be noted that it is specifically provided that committees of the Society, except those dealing with the Society's domestic affairs and joint committees with other bodies, have power to suggest to the Council the names of additional members who may, or may not, be Fellows of the Society; and, in fact, many of the Society's committees include non-Fellows who are brought in for their special knowledge in a particular field.

The Royal Society now consists of some six hundred Fellows and foreign members. Broadly speaking, the fellowship is representative of the whole range of natural science. That this should be so is in part the result of the method of election. Candidates are proposed by Fellows on the basis of their scientific achievements. These nominations are scrutinized by the Council, which selects by ballot a limited number annually; at present the number is twenty-five. It is not always realized that in making its recommendations for election to the fellowship, the Council takes account of the general balance of subject interest among the Fellows; by this means it is ensured that all subjects are represented, and the domination of the Society by sectional interest is avoided. This form of election has been criticized, but it seems to provide the general balance of interest required. In addition, the Council has the power to nominate for election "persons, who . . . either have rendered conspicuous service to the cause of science, or are such that their election would be of signal benefit to the Society"; the numbers are, however, limited to one a year unless no election has been made in any year, in which case two nominations can be made in the following year. Foreign members are nominated from time to time on the grounds of the eminence of their scientific attainments, but not more than four can be elected annually. Ordinary fellowship of the Society is limited to British subjects and citizens of Eire. Women were tardily admitted to the Society under a curious statute which reads: "Nothing herein contained shall render women ineligible as candidates".

Human institutions which have survived for three hundred years are sufficiently rare in these days of continual and ever-increasing pressure of events to be worthy of special comment. The present high esteem in which the Royal Society is held throughout the world is due in part to the eminence of its Fellows, and in part to the wisdom with which it discharges its responsibilities to science and to the nation. It can now enter on a further century of endeavour, adding to the reputation which has been steadily built up over the years, and sustained by the good wishes of scientists throughout the world.

members; and while the Association is given wide latitude, such financing is intended to be for purposes which are of high priority for development in the light of the needs of the areas concerned and, except in special circumstances, for specific projects. Moreover, finance is not to be provided by the Association if, in its opinion, such finance is available on reasonable terms from private sources or could be provided by a loan of the type made by the International Bank. Article I, in fact, defines the purposes of the Association as to provide economic development, increase productivity and thus raise standards of living in the less-developed areas of the world included within the Association's membership, particularly by providing finance to meet their important developmental requirements on terms which are flexible and bear less heavily on the balance of payments than those of conventional loans.

The Association is thus intended to further the developmental objectives of the International Bank for Reconstruction and Development and to supplement its activities. As Mr. Barber explained in the House of Commons, the International Bank itself is not designed to help countries with sound and important development projects which they are unable to finance simply because of the weakness of their balance of payments. The new Association will be empowered to lend in such cases on special terms which may, for example, include a long period of repayment, or a period of grace before repayment commences, or even waive interest for an initial period. Apart, however, from being complementary to the work of the International Bank, Mr. Barber pointed out that linking the Association with the Bank is also a matter of confidence and will enable the Association to operate as a going concern from the start.

In commending the Bill to the House of Commons, Mr. Barber also referred to the considerably enlarged part Great Britain is now playing in providing assistance for overseas development; but our capacity to do more, he said, is inevitably limited. The commitment to contribute to the International Development Association had been foreseen for some time, and the Government has decided to give priority to this measure to supplement the existing operations of the International Bank and to increase the united funds available for development. This point of view was generally welcomed in the House of Commons, although Mr. H. A. Marquand and some other speakers questioned even so whether enough is being done for the under-developed areas.

Mr. Marquand referred particularly to the White Paper, "Assistance from the United Kingdom for Overseas Development"*, also mentioned by Mr.

Barber which sets forth both the growth and the present magnitude of this effort. From £61 million in 1951–52, after a decrease to £49 million in 1952–53, this has increased, apart from a slight recession in 1956–57 and 1957–58, to £110 million in 1958–59 and an estimated £138 million in 1959–60. The bulk of this takes the form of grants, loans and payments for technical assistance under arrangements made directly with the recipient country, totalling £86·1 million and an estimated £117·7 million in 1958–59 and 1959–60, respectively, compared with £23·4 million and an estimated £20·7 million in contributions to international bodies working in this field.

Under the former, described as bilateral assistance, is included that given to the Colonial territories, for which altogether some £220 million was made available under the Colonial Development and Welfare Acts during the period 1946–60; of this total, about £45·5 million was unspent by March 31, 1959. Subsequent legislation has provided an additional £95 million for the period up to March 31, 1964, and of the figures already quoted for 1958–59 and 1959–60, £49·4 million and an estimated £62·7 million are for the Colonial territories, £26 million and an estimated £40·6 million for the independent Commonwealth countries and £10·7 million and an estimated £14·4 million for other countries. These figures include a considerable contribution to education, though such expenditure is not distinguished separately in the White Paper, and contributions to technical assistance totalling £4·4 million in 1958–59 and an estimated £5·2 million in 1959–60.

This technical assistance may be provided for Colonial territories through the Colonial Office, and to independent countries of the Commonwealth and to other countries under arrangements made direct, under the Colombo Plan, and through the Foundation for Mutual Assistance in Africa South of the Sahara and the Central Treaty Organization. For example, the cost of training 473 out of 2,181 officers in the public services of the Colonial territories, who in 1959 attended training courses in the United Kingdom, was met from Colonial Development and Welfare Funds, and in the past five years the Post Office has trained more than 1,000 people from overseas in postal, telephone and telegraph operations and in telecommunications engineering. The White Paper refers also to the work of the Overseas Research Council and of the various advisory bodies on Colonial Research without, however, giving any estimate of expenditure on scientific research in this way.

When private investment of about £100 million is taken into account, the White Paper estimates that about 1·25 per cent of the national income of the United Kingdom goes to benefit the less-developed countries, and since the War some £2,500 million has been devoted to those countries from United Kingdom sources in the form of private investment and Government assistance. Such assistance can only be provided if the economy of the United Kingdom continues to develop on the right lines, and the Minister of State for Commonwealth Relations, Mr. C. J. M. Alport, was at pains to stress this aspect in winding up the debate from the Government side. Incidentally, it should be noted that, as Sir Henry d'Avigdor-Goldsmid pointed out in the debate, the Association is specifically empowered to provide technical assistance and advisory services at the request of a member, and such assistance may, at the discretion of the Association, be provided with or without reimbursement.

The brief debate when the Bill received its second reading in the House of Lords on May 17 followed rather different lines. In introducing the Bill for the Government, the Earl of Dundee said that the United States and Japan have already introduced legislation to provide for the adherence of their countries to the Association, and pointed out that the Bill is only part of a general effort to assist the more-undeveloped countries of the Free World. He also suggested that it is more scientific to measure our effort as a percentage of our exports rather than of our national income; that figure is about 7 per cent and not 1·25 per cent. He also quoted the reference in the communiqué from the Conference of Commonwealth Prime Ministers to the desirability of co-operative action among members of the Commonwealth in assisting the economic development of Commonwealth countries in Africa which have recently attained or are approaching independence. Indeed, the Conference had recognized the urgent need to maintain, and where possible increase, the flow of economic assistance to the less-developed countries and had specifically welcomed the decision to establish the International Development Association.

Lord Ogmore, in welcoming the Bill, stressed particularly the importance of technical assistance, and in this connexion he said that in his experience in the past few years one of the greatest shortages in the under-developed countries had been in competent managers. They are short also of people with technical experience at the professional and the technician-level, and this could greatly affect the execution of a scheme; he was glad that the Government has already recognized the importance of technical training for apprentices. In his reply for the Government, the Earl of Dundee directed attention to the powers which Sir Henry d'Avigdor-Goldsmid had noted in the House of Commons.

The bearing of the International Development Association on technical assistance is not the only reason why the new Act merits some attention from the scientist and technologist. Finance is not the sole consideration which determines the possibility of particular schemes. Both the debates in Parliament and the White Paper on Assistance from the United Kingdom indicate how complex have now become the relations between the overseas territories and the Colonial Office and the Office of Commonwealth Relations. These relations have not been adequately debated, but with the increasing number of Commonwealth overseas territories which have attained or are on the verge of independence, strong arguments can be advanced for reviewing the relations between the Colonial Office and the Commonwealth Relations

n their own initiative in the
nis apart from the risk of them
becoming Communist States in the meantime. This, Mr. Shonfield believes, would be a further obstacle, for he is convinced that the West could give these countries the fruits of modern technology more quickly than they could possibly obtain them otherwise.

Mr. Shonfield is optimistic as to the generosity of the West, but he is very realistic as to the sustained good sense that will be required and the readiness to compromise, at least in the early stages of development, with many of our cherished ideals and standards. The International Development Association is indeed a welcome step forward, but much more will be required. Apart from constructive thinking about the whole structure of government as it affects the conditions of service and operation, there must be real determination to use to the full all existing instruments such as the Colonial Development Corporation and the Overseas Research Council.

SPACE RESEARCH

Satellites and Scientific Research

By Desmond King-Hele. Pp. xii+180+6 plates. (London: Routledge and Kegan Paul, Ltd., 1960.) 21*s*. net.

THE launching by the U.S.S.R. on October 4, 1957, of the first artificial Earth satellite may be said to have opened the era of outer-space research. Subsequent developments have been rapid. The second *Sputnik* was launched by the U.S.S.R. on November 3, 1957. The first successful launching of a satellite by the United States occurred on February 1, 1958. Since then the Americans have successfully launched several more satellites. In addition, space vehicles (*Luniks*) have been launched by both the Russians and Americans, some of which will orbit the Sun and may be termed artificial asteroids. The Russians have succeeded in hitting the Moon with one of their *Luniks* and transmitting a photograph of the back face of the Moon by another.

This book is concerned solely with the artificial satellites, the equipment installed in them, the purposes for which the equipment was designed, and some of the scientific results that have been derived. The preface is dated April 1959, only 18 months after the first successful launching of a satellite, though mention is made in the text of the launching of the three American satellites, *Explorer* 6 on August 7, 1959, and *Discoverers* 5 and 6 on August 13 and August 19, 1959, respectively. Brief reference is also made to the launching of two space-vehicles, the Russian *Mechta* or *Lunik* on January 2, 1959, and the American *Pioneer* 4 on March 3, 1959.

A satellite can provide scientific information in two ways. In the first place, careful tracking of the orbit of the satellite and of the changes in the orbit with time can provide information in two directions. The equatorial bulge of the Earth causes the orbital plane to rotate slowly about the Earth's axis, in the opposite direction to the satellite's motion. From the analysis of these changes in the orbital plane, the ellipticity of the Earth's figure can be derived and also some information about any asymmetry of the Earth about its equator. The drag of the atmosphere on the satellite produces progressive changes in the shape of the orbit, the distance of the satellite at apogee decreasing more rapidly than the distance at perigee, so that there is a progressive reduction both in the orbital period and in the eccentricity of the orbit. From the changes in the shape of the orbit information about the density and temperature of the upper atmosphere at different heights can be inferred. The information that has already been derived from the study of these orbital changes, to whose analysis the author of this book has made substantial contributions, has substantially modified previously accepted ideas. This information is independent of any instrumental equipment carried in the satellite.

In the second place, each satellite is provided with instrumental equipment designed to obtain information in specific directions from coded signals telemetered to the Earth. Some striking and unexpected information has already been obtained, though more information will become available when the signals have been fully analysed.

The value, f, of the ellipticity or flattening of the Earth, that has already been derived from the satellite data is $1/f = 298 \cdot 20 \pm 0 \cdot 03$. The value previously accepted, derived from geodetic data and from the analysis of changes in the Moon's orbit, was 297·1. The change is substantial; the previously accepted value was based on many investigations, which had given reasonably accordant values. It is also tentatively inferred that the Earth is slightly asymmetrical about its equator (slightly pear-shaped), the north pole being about 50 ft. higher and the south pole about 50 ft. lower than on a spheroidal earth. This conclusion is not yet definitely established; further observations will eventually lead to a more accurate result. It is to be expected that higher terms in the gravitational potential field of the Earth will in course of time be evaluated, when data from a number of satellites with differing orbital inclinations have become available for analysis.

The analysis of the changes in the shape of the orbits has led to the definite conclusion that the density of the atmosphere decreases more slowly with height than had previously been believed, largely from the extrapolation of data provided by rockets. At heights of 120–250 miles, the atmosphere is 3–11 times more dense than was previously believed. The inferences about the temperature of the atmosphere at these and greater heights are as yet only tentative, though it appears that at great heights the temperature is considerably higher than has hitherto been supposed. There is also some evidence that the air density at heights of 100–500 miles varies with a period of about 27 days, being presumably influenced by solar activity.

The most striking discovery so far obtained from the instruments carried by satellites is the existence of two belts of hitherto unsuspected intense radiation around the Earth which are attributed to charged particles trapped by the Earth's magnetic field. Much more information will in the course of time be obtained about these belts, their nature and their changes. It is thought that the inner belt may be caused chiefly by cosmic-ray debris and be composed mainly of protons, while the much larger outer belt is fed by particles from the Sun and is composed mainly of electrons. The further study of these belts will provide information about the aurora and about the Earth's magnetic field.

Such wide interest has been aroused by the launching of satellites and space probes that this book, describing how and what information has been derived from satellites, is very timely. It is written so far as possible in non-technical language, and is well illustrated with many figures. The author has given an extensive list of books and scientific papers relevant to each chapter, which will be of use to those who wish to obtain further information on any of the subjects discussed in the book.

H. SPENCER JONES

CYBERNETICS AND MANAGEMENT

Cybernetics and Management

By Stafford Beer. (Management Science Series.) Pp. xviii+214. (London: English Universities Press, Ltd., 1959.) 25*s.* net.

IT is a sign of the importance of cybernetics that eleven years after Weiner defined the study of control mechanisms as a new discipline, inquiries about its nature and utility have become more topical and not less so. In directing his contribution on this topic to the "scientifically educated and imaginative manager", Beer recognizes that such interest extends well beyond academic halls.

Approaching a brief answer to the general question, Beer says the importance of cybernetics derives from the backwardness of the concepts of 'control' that prevail in our society. For cybernetics, control is an attribute of system function, an attribute that may be produced by diverse and sometimes quite subtle means. The diversity of their controls makes biological systems valuable models for industrial cybernetics.

In industrial application, cybernetics is not solely concerned with automation on the assembly line. Indeed, its main target is managerial: a control device, seeking optimal strategies, amplifying the intelligence of its human components, learning from experience and adapting itself to its environment. The 'device' is quite general, includes not only computers and other hardware but also methods of organization, of fact finding and of decision making that involve human agents. Present managerial methods, with all their various components, are instances of such systems. Moreover, because they show goal-seeking behaviour and attempts to maintain equilibria against varying disturbances, they belong to the general category of 'homeostat' that includes many biological systems as well.

Its jacket describes this book as a presentation of the basic principles of cybernetics without a mass of mathematics. Such a presentation it certainly contains, and delightfully clear it generally is. In places, however, a surfeit of detail and perhaps a few tracks of hobby horses tend to obscure the main trail of the description. Nine pages of preface and seven pages of connective summary, possibly designed to rectify this 'noise', will aid the selective reader to follow the main thoughts. In his role as a philosopher he will be well rewarded.

For the reader as a manager the value of this doctrine is not so clear. He will regard this as the second major move in fifteen years to construct a managerial science. The sphere of the first, operational research, was more limited than that of industrial cybernetics. It functioned within, as part of,

with the environment. The world of the ancient Greeks or of the contemporary 'organization man' are something more than mere extensions of the habits of our simian ancestors. As he puts it rather colourfully at one point (p. 308): "If it is katydid nature to scrape, frog nature to croak, warbler nature to warble, it is human nature to play the *Air for G String*". The potentialities of human nature must lie beyond the limited historical and social expressions of it that we know at present.

In putting forward his plea for the larger view of human nature, Dr. Murphy takes fully into account the evidence of our grosser individual limitations. He dwells at length on such matters as the development of fixed habits of thinking and perceiving which blind the individual to culturally unpopular viewpoints. Although the increasing tendency to standardization of thought and feeling in modern society clearly threatens to stifle creativity, he gives reasons for hoping the creative urge may win through.

In the field of genetics, for example, he points out that the scope for evolutionary change is greater than is generally appreciated. Concentration on the effects of pathological genes has diverted attention from the inheritance of variations of temperament, and from the possibilities of readier manifestations of particular attributes in particular environments. Some stocks may be increasing in numbers and others decreasing so as to alter the predominant temperamental patterns of the group. Qualities of sensitivity and of equanimity could be gaining at the expense of toughness and aggressivity. Just as height is increasing (perhaps due to favourable environment and especially nutrition) so may be capacities of learning and intelligence.

In his more far-reaching speculations Dr. Murphy seems to imply that highly organized groups develop a life of their own beyond the individual personalities involved. Artistic and scientific achievements ultimately become impersonal or interpersonal. In the findings of telepathy research, it appears as if the individual consciousness reaches out so that the boundaries between mind and mind or between mind and the environment become blurred.

Scorning the traditional timidity of the social psychologist in the face of value systems and judgments, Dr. Murphy plunges into discussion of political systems. He sees the present day as a period of crisis in which man may destroy himself in atomic conflict before intelligent control of social development becomes possible. For the immediate future the most hopeful prospect seems to be a rapid economic development. In this the West may overtake their opponents, who will end up by capitulation or imitation, or the two camps may both progress so fast that their leaders can allow peaceful competition between the two systems for some time to come. If this respite is allowed us, then humanity will have time to choose between such possibilities as an authoritarian hierarchy or a leaderless, group-centred life on the ant-hill model. Among these long-range prospects he sees the greatest hope of a viable civilization in some system in which the governing forces are reliably guided by intelligent feed back from the middle and lower levels. Any such system would call for revolutionary development of education, and also freedom to indulge individual artistic and cultural interests beyond the immediate needs of the corporate technocracy. At present education tends to be too didactic, geared too closely to the task of imparting technical skills, instead of encouraging creative thinking and discussion among the young on out-of-school family and community problems.

Because of the range and complexity of the problems discussed this book cannot be digested quickly nor reviewed comprehensively. But it is well worth studying from cover to cover. D. J. WEST

FOSSILS FOR THE NATURALIST

Fossils

By Prof. H. H. Swinnerton. (The New Naturalist: a Survey of British Natural History.) Pp. xiv+274+25 plates. (London: William Collins, Sons and Co., Ltd., 1960.) 30*s.* net.

THE volumes of Collins's New Naturalist Series are delightfully produced books, splendidly illustrated and written by acknowledged authorities. They make ideal presents, and are a delight to possess. It is also true that most naturalists are born collectors; and these books are eminently collectable. But these facts do not alone explain the success of the series. It succeeds because these books are mostly written by naturalists for naturalists. They appeal to the faculties of wonder and delight in Nature which (rather than the spirit of curiosity and the pure desire for knowledge) are the particular characteristic of the naturalist. The present volume, the forty-second of the Series, is no exception. It is in the direct line of descent from Hugh Millar and is a naturalists' book and not just another popularization of science.

Prof. H. Swinnerton's approach to his subject is historical in two different senses. He is most successful in conjuring up pictures of the successive extinct faunas and floras in which the animals and plants are brought vividly before us as living things in their changing natural environments. We follow in separate short chapters the evolution of the main phyla of plants and animals, first in the Palaeozoic, then in the Mesozoic and finally in the Cainozoic. At the same time, by a series of cleverly interwoven digressions, we learn of the history of the growth of palaeontology, and our interest is cunningly sustained by stories of the lives of many of the collectors and research workers whose discoveries he describes. It is all very well done, and the book is eminently readable.

All this being said, it is the more unfortunate that an unqualified welcome cannot be given to this book which at first sight seems so well to fill an obvious gap in the New Naturalist Series. It is not that the vividness of the reconstructions of the geological past is often obtained by the presentation of detail the conjectural nature of which is not made sufficiently apparent. Nor, since the book is not intended for palaeontologists, does it matter much that a number of names used are out of date, as are also some of the ideas (for example, the derivation of *Caninia*, *Palaeosmilia* and *Dibunophyllum* from '*Zaphrentis*' in the Lower Carboniferous, and other ideas about the evolution of corals and graptolites). The pity is that there are a number of confusions of matters of some importance.

Thus it is regrettable that the graptolite zooid is described as possibly not unlike a hydroid polyp, while the dendroid graptolites are said to be comparable with *Cephalodiscus*. It is also unfortunate that the old classification of the East Anglian crags in the Pliocene is retained, especially as confusion is created by the remark that the deposits underlying the Cromer Forest beds have been shown to be of Pleistocene age. This particular confusion is worse confounded by the caption to plate 21, "Marine Fossils of the Quaternary", which illustrates both crag and Eocene fossils. Presumably for Quaternary, Cainozoic should be read. Other confusions are of serpulite (*Salterella*) with *Serpula*, the alleged presence of *Archaeocyathus* in Scotland and the inclusion of the reindeer in a list of extinct animals.

The illustrations are, with one or two notable exceptions, well chosen and well reproduced. However, there are several illustrations where a number of fossils are represented on very different scales without any indication of the relative or absolute size of the specimens. Finally, it is necessary to say that there are far too many misprints, and that these chiefly affect the descriptions of the plates (at least fourteen corrections required). S. SIMPSON

THE FIRST DECADE OF DDT

DDT

The Insecticide DDT and Its Significance. Edited by Paul Müller. Vol. 2: Human and Veterinary Medicine. By W. J. Hayes, Jr., S. W. Simmons and E. F. Knipling. Edited by S. W. Simmons. (Lehrbücher und Monographien aus dem Gebiete der Exakten Wissenschaften, Chemische Reihe, Band 10.) Pp. 570. (Basel und Stuttgart: Birkhäuser Verlag, 1959.) 66 Swiss francs; 66 D.M.

THIS second volume of a series on DDT contains three contributions by American authorities on insecticides and their use: "Pharmacology and Toxicology of DDT", by W. J. Hayes, jun.; "The Use of DDT Insecticides in Human Medicine", by S. W. Simmons, and "The Use of DDT in Veterinary Medicine", by E. F. Knipling. The first two of these are almost equal in length and comprise about 400 pages of the book, each concluding with a list of some 600 references; the shorter veterinary section has about 200 references.

Dr. Hayes deals first with clinical, pathological and physiological aspects of DDT toxicity as observed in animals. Human toxicity risks are then discussed from data on experimental and accidental intakes by man, on workers handling DDT, and in relation to DDT residues accumulating in water, in milk or in foodstuffs derived from treated animals or vegetable sources. This is summed in terms of administrative policies for toxic residues in general in consumable goods. DDT is safe when used as recommended. Hazards to domestic mammals, birds and insects (bees notably) and to various forms of wild life from medical and veterinary usages of DDT form concluding chapters to the section.

The contribution by Dr. Simmons (also editor of this volume) is not merely about DDT for the control of arthropods of medical importance. It is valuable and noteworthy for its emphasis, well illustrated graphically, on the effects of vector control by DDT on the incidence of the diseases concerned. Much of this part of the work is about mosquito-borne infections and mainly on malaria control, arranged geographically. Other chapters are on other biting flies, houseflies, lice, fleas, triatomid bugs and on the mites and ticks. The acarines are less susceptible to DDT than the insects. It seems scarcely justifiable, in view of general experience and what is recorded in the relevant text, that, for example, scabies and

a discussion of the incen-
warfare, culminating in the
led the Crusaders and which
he Byzantine Empire. Many

of these ancient incendiaries contained one of the numerous types of crude oil found in Mesopotamia or the regions north of that country. The author believes that the basis of the earliest Greek fire was liquid rectified petroleum or volatile petrol, which was projected in hand-grenades, or ordinary petroleum in tubs shot from *ballistae*. The mixture of petrol and resinous substances, thickened into a jelly, and the mechanical means of projecting it constituted the invention of Greek fire, an achievement of chemical engineering.

In his second chapter the author turns to the examination of "The Book of Fires of Mark the Greek", which he compares with passages from Albertus Magnus's "De Mirabilibus Mundi" and Roger Bacon's "De secretis operibus artis", from which he concludes that there seems to be no reasonable doubt that Roger Bacon was well acquainted with the preparation and properties of gunpowder, though probably ignorant of its use as a propellent. He may have derived his knowledge about its composition from the "Liber Ignium", which is probably of Arabic origin.

The next chapter is devoted to the "Legend of Black Berthold", the imaginary German monk said to have invented gunpowder and cannon. The earliest picture of a cannon is found in an English document, its earliest mention in an Italian one of 1326. He then proceeds to discuss the earliest English, French, Burgundian, German and Italian cannon and their nomenclature. A further chapter discusses miscellaneous fifteenth-century treatises on military arts and their knowledge of the use of gunpowder and firearms, mines and rockets.

Chapters 5 and 6 are devoted to a systematic discussion of gunpowder and firearms in Muslim lands and in China. Here the author dispels many erroneous statements of earlier authors by carefully examining the original texts and consulting such experts as Holmyard and Needham. His conclusions are that saltpetre was known under the Sung dynasty (A.D. 960–1279), and that around 1044 certain 'proto-gunpowder' mixtures were used in bombs but not as propellents. About 1233 we find the prototype of a gun described in Chinese literature, and true gunpowder was known towards the end of the Mongol Yuan dynasty (A.D. 1260–1368), when it was also known in Europe. Though there is a possibility that gunpowder was discovered in China, we are not certain that cannon were invented in that country; as the information about cast-iron Chinese guns, said to date back to 1356, is unsatisfactory. The Arabs seem to have introduced gunpowder from the East, first using it as an incendiary like Greek fire. Cannon and firearms seem to play a part from the fifteenth century onwards only in Ottoman warfare.

The last chapter is devoted to the history of saltpetre. Here the author could have consulted with profit M. Levey's essays on chemical technology in ancient Mesopotamia rather than the much older evidence he quotes; although his discussion of the classical and post-classical evidence of this most important ingredient of gunpowder is excellent and provides us with many useful data on the ancient manufacture of saltpetre.

Prof. Partington has again given us a handbook which not only the artillery expert and the chemist but also the historian of technology will consult with profit for many years to come.

R. J. FORBES

Birds in Colour

Illustrated by Karl Aage Tinggaard. With descriptions by Bruce Campbell. Pp. 103+256 plates. (Harmondsworth, Mddx.: Penguin Books, Ltd., 1960.) 21*s*.

IT must be exceedingly difficult to produce yet another moderately priced book on birds that has its own merits and justifies itself as a purchase both for beginners and experts. The compiler of "Birds in Colour" has managed to do this by producing an outstandingly straightforward reference book that makes bird recognition comparatively easy for "those who go about in the towns, in the country and by the sea in the British Isles—and those who look observantly out of their kitchen windows"; at the same time producing a very beautiful book of pocket-size.

The book has two main sections. First, there are 256 coloured paintings of all the birds likely to be seen and recognized in the British Isles, arranged, roughly, in the Hartert order. Each bird takes up half a page, and similar birds, likely to be confused, are on adjoining pages. This makes it possible for four similar birds to be compared at a glance. The second part of the book is devoted to the descriptions, which bear the same number as the paintings earlier in the book, thus enabling speedy reference. This section gives such information as habitat, appearance, voice, habits; and a very helpful note on the other birds with which this one is likely to be confused. This is particularly helpful for a beginner. At the end of the book is a short section of flight sketches, followed by a list of books to read, an index of Latin names, and, lastly, an index of English names.

The book is of the standard 'Penguin' size, but has a stiff, colourful cover, and each of the 256 paintings are not only realistic but also pleasing to the eye. The simplicity of the book is its main asset, as, while giving the maximum help in bird recognition, it avoids all technical terms and irrelevant data. All essential points are lucidly written—fitting companion notes for the Danish artist's paintings, which cannot be too highly praised.

B. J. G. MAITLAND

Flat Rolled Products

Rolling and Treatment. Edited by T. E. Dancy and E. L. Robinson. (Metallurgical Society Conference, Vol. 1.) Pp. xix+128. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1959.) 30*s*.

THIS book, the first of a series on various branches of metallurgy, is a report of the proceedings of a conference arranged by the Mechanical Working Committee of the American Institute of Mining, Metallurgical and Petroleum Engineers, all the contributors being connected with steel firms in the United States or in Canada. To this extent, the title may be somewhat misleading, since non-ferrous practice is touched on only by implication.

Six papers are included of which half the book is devoted to two on the factors affecting strip profile in hot- and cold-strip mills and on the closely related influence of hot-strip profile on subsequent operations. The remaining contributions are concerned with heat-treatment practice, the continuous normalizing of flat-rolled products, the continuous annealing of deep-drawing sheet and the theory and evolution of coil-heating practice in steel mills.

To the reviewer the most interesting part of these proceedings is a two-page paper dealing with the annealing of strip in liquid sodium. Considerable laboratory work has been done during the past few years with results sufficiently encouraging to justify pilot-scale operation. The main advantages envisaged include increased rapidity of heating and cooling, a reduction in the space required and lower maintenance costs due to simplification of the plant.

F. C. THOMPSON

The Nuclear Handbook

Consulting Editor: Prof. O. R. Frisch. Pp. xv+640. (London: George Newnes Ltd., 1958.) 50*s*. net.

THIS book is described in the foreword as having been designed as a day-to-day reference for use by scientists and technicians working in nuclear science and related fields. There are nineteen sections of varying length written, generally, by specialists. The topics include, among others, the nuclear properties of isotopes and natural radioelements, and of fission product and transuranic elements; the theory of nuclear reactors and the properties of fuels and other materials used in them; and related technologies such as particle accelerators, vacuum techniques, and electronics

The technical level and the style of the contributions vary a good deal. The first section, for example, contains an elementary description of the structure of the atom whereas the mathematical discussion of nuclear reactions in section 19 makes few concessions to the unsophisticated. This last section consists of a collection of equations and formulæ, with tables and graphs, connected by the minimum of narrative; the section on natural radioactivity is prefaced by two pages of history beginning with Becquerel.

The "Handbook" was published shortly before the second Geneva Conference on atomic energy, so that some of the data were outdated within a short time of publication. Nevertheless the book is a compact source for a wide range of information and should be useful, provided that reference is made to the periodical literature to check data in fields known to be changing rapidly.

K. E. B. JAY

Guide to Reference Material

Edited by Dr. A. J. Walford, with the assistance of L. M. Payne. Pp. viii+543. (London: Library Association, 1959.) 80*s*.; 12 dollars. (Members of the Library Association, 60*s*.; 9 dollars.)

THIS volume provides an annotated list, classified on the 1957 abridgement of the Universal Decimal Classification, of leading reference books and bibliographies, with emphasis on current publications and particularly material published in Britain. Maps, anthologies and most source books have been omitted, as well as the vast majority of periodicals, but in certain scientific and technical subjects, textbooks have been included, for want of more comprehensive works. It is intended for librarians, in the building up and revision of reference library stock; for use in general and special library work; and for students taking the Library Association examinations. Its 3,000 selected entries are the result of the work of some 70 contributors, and an admirably produced volume is well designed to serve as a point of departure for a much-needed series of detailed annotated guides on specific subjects, as is the hope of the editor, Dr. A. J. Walford.

famous author of "The Sceptical
in many tongues, devoted the leisure of a great gentleman to a life of study and was renowned not only for his learning but also for his piety, his religious and moral writings being probably as numerous as his scientific works.

A very different figure was Sir Robert Moray, who combined the qualities of a scholar with those of a man of action. He had served as a soldier under Louis XIII and had been with King Charles in France. After the Restoration he held public offices, enjoyed the confidence of the King and was described by Huygens as the soul of the Royal Society, to which at various times he made communications on geology, natural history and comets. He has been spoken of as a chemist and a mathematician and, according to Pepys, was interested in music.

A man who in the opinion of some deserves to be thought of as the real originator of the Society was John Wilkins, warden of Wadham College, Oxford, and later Bishop of Chester, wise, tolerant, conciliatory, continuing his work both under Protector and King. He was the central figure around whom gathered the group of learned men which later turned itself into the Society. He had a forward-looking mind, and not only wrote a work on the Moon as a habitable world but composed also a discourse on the possibility of a passage there by 'volitation'.

There are philosophers of history who would maintain that the Royal Society had to come into being when it did, irrespective of individuals, because the climate and temper of the age demanded it. They may be right. It must needs be, perhaps, that such things come, but all honour, nevertheless, to the men by whom the necessity is fulfilled. If the individual does not determine the event he profoundly influences the manner of it.

These men, in whom the elements were thus diversely mixed, initiated the humane tradition of the Society, the union of thought and action, the partnership between men of the study and men of the world, which has been maintained throughout its existence, is preserved, we would like to hope, to-day, and will decide its future.

In illustration of a preconceived thesis, the reception of the new Society could be represented in diametrically contrasted manners. Names like Christopher Wren, John Evelyn, Samuel Pepys and John Dryden bear witness to the width of its appeal. Could we indeed quote anything like so varied a list at the present time? The sympathy of the literary world was not lacking. Addison styled Robert Boyle "an honour to his country", persons of consequence consigned their sons to the care of Warden Wilkins, and the patronage accorded to the Royal Society by established authority was neither purely formal nor mere lip service. Prince Rupert made communications on his own account. The Earl of Sandwich, sent to escort Catharine of Braganza from Portugal, allowed himself to be set the task of making observations for the Royal Society on the tides and on the saltness of the sea. The King himself was on terms of friendly intimacy with many of the members, often visiting with Sir Robert Moray the laboratory established in Whitehall.

---

* A
Londo

the Formal Opening in the Albert Hall,
ary Celebrations on July 19.

If the illumination is suitably adjusted, however, a less-mellow picture emerges. The Warden of Wadham might be a leader of the new movement: Dr. Fell, the formidable dean of Christ Church, would have none of it. The Public Orator of the University of Oxford declaimed against the Royal Society in the Theatre built by Wren, and Antony Wood declared it to be an obnoxious body. Bishop Wilkins, Bishop Ward and Bishop Sprat might defend the new philosophy with every strength of argument and eloquence, Robert Boyle might write the "Christian Virtuoso", every protestation and example of piety and orthodoxy might be offered by the Fellows, none of this prevented attacks from the pulpit, and the strangest accusations from other quarters.

The complaints openly made by the objectors were of atheism, impiety and subversion, or if not the practice or countenancing of these things then at least the creation of a philosophy which would lead the weaker brethren into evil thoughts or be used by the wicked as a cloak and excuse for their depravities. Besides operating on the side of the godless and corrupting the innocent, the Royal Society was at the same time supposed (though scarcely, it may be presumed, by Catholics) to lend itself to popish schemes. It elevated sensual ideals, and it encouraged great expense of spirit in the pursuit of vain truths. It might challenge the authority of the universities and invade the province of the physicians.

Much of this was still reverberating yesterday and even lasts to-day, and in this respect the three centuries assume perhaps their shortest perspective. In our own time scientific studies have received extravagant praise and intemperate criticism. One great novelist of this century saw the millenium about to be realized through science. Lesser literary figures of the moment have laid every defect or misfortune, from intellectual arrogance to social obscurity, at its door.

Every complaint and reproach levelled in the seventeenth century, every fear expressed, every resentment, interested or disinterested, openly or secretly working, can be paralleled in the recent past. Every anxiety, misgiving, criticism or reserve voiced to-day has been countered by the seventeenth-century apologists. Nor can the threat of destruction by the release of nuclear energy really have aggravated the issue, for the perils of atomic warfare are at least no more terrible than the prospects of eternal damnation to which many in the earlier age believed the new doctrines were leading men.

If criticism could have restrained or gibes deterred, if any combination of polemic and persuasion could have mollified or silenced, the issue would have been settled once for all. But these strange contests of seemingly incompatible philosophies have periodically renewed themselves, rising to great climaxes like the controversy over evolution in the nineteenth century and the quarrels about the use of nuclear energy in the twentieth century. The origin lies more in emotion than in reason: genuine fear of the unknown, reverence for established things, but most of all in the strangely partisan instincts of men, the manifestation of their combative and yet gregarious nature. What happened after the foundation of the Royal Society was largely a reflexion of a permanent or at least a strongly persistent pattern.

But the most significant circumstance is that the attitude of the world at large probably did not seriously determine the course of science. In the seventeenth century the contest was largely a battle of the books. The opponents of the Royal Society did little effectively to hinder it. For indeed, after the first flush of enthusiasm, did the majority of its non-scientific or fashionable supporters do very much actively to help it. The record of sermons, pamphlets and other forms of the written word is the raw material of a one-sided story. The literary basis of so much history can easily falsify the perspective. Writers express their views and other writers, by the natural working of affinity, often attach undue importance to the evidence that these afford. A few dramatists can characterize a whole period as licentious, even resolutions of undergraduate debating societies if they catch the fancy of the journalists may help to fix a label on an age. But the future germinates unknown and silently.

From the time of the foundation of the Royal Society onwards there was a steady increase in the number of dedicated men who, by the concentration of their minds, the skill of their hands and the sweat of their brow, worked to uncover the secrets of Nature. Their labours were largely unknown to their contemporaries; they are but perfunctorily recorded by historians, and yet they have ended by transforming the face of the globe and the life of humanity. The literary battles of the detractors, the satirists and the apologists had little effect. The men of science lived up to the motto proposed for the Royal Society by Evelyn *Nullius in Verba*, accepted the authority of none, and were on the whole unmoved by praise or blame.

The nature of things is such that two of the early criticisms of science have refuted one another. It was, some said, too much concerned with material ends: it indulged, according to others, idle curiosity to the good of nobody. The answer to-day is clear. The technology which has transformed practical existence is largely an application of what was discovered by these allegedly irresponsible philosophers. On the other hand, their shortsighted and earthy preoccupations have entrained an upheaval of the whole of human thought. By what strange workings of destiny does this come about? The propounding of ambitious practical aims seldom leads to their fulfilment. "Find me a way" an ancient despot might have said, "to send invisible messages round the world, and I will ennoble and enrich you". The reward would never have been won. "Find out", he might less plausibly have said, "about the strange force in this little piece of amber". This apparent frivolity contained the secret of his first requirement, but remote and unforeseeable.

The full fruition of scientific work depends upon three things: the desire to know, the initiative to find out and the awareness to apply. Highly special conditions have to be fulfilled before the plant will bloom, before the flower will fruit and before the fruit will ripen.

Let us have no illusions about one thing. To-day we commemorate the doings of a minority and of a small minority. The King himself was a rare figure among the rulers in history. The glamour shed on the Royal Society by his patronage ensured the respect of the eminent but not their subscriptions, and in the year 1700 the corporate income did not exceed about £100.

But if the men of science did not continue to receive much material support they were not for that reason without significance to their time. Who is representative of an age? The acclaim of the day seldom anticipates the verdict of posterity, since the germinal things are almost always hidden or unrecog-

iology has joined with chemistry to create the modern art of medicine. All the sciences have now converged on the study of life, from the simple cell to that most wonderful of instruments—the human brain.

In the last hundred years the pattern of daily life has been transformed. Things which in the reign of Charles II would have seemed like the dreams of visionaries or indeed the impostures of charlatans are now part of the common scene. Flight, speech and vision across the world, cures as by miracle from deadly illnesses, machines to which men delegate heavy toil, dextrous manipulation or mental exertion far beyond their own unaided powers, colours surpassing the rainbow in variety, all these things and more have come into being. The keys to unlock atomic energy have placed in man's hands undreamed of powers which he may use for good or evil. The keys which unlock some of the secrets of human personality are slowly being cut, and men may soon be using them to do we know not what.

Is this not history ?

In the realm of ideas the story has been even stranger and more turbulent. The conception of the universe as a mechanism suggested a materialistic view of all existence, though not to Newton himself, and possibly less often to men of science than to onlookers unconscious of the real intention of scientific hypotheses. The time-scales revealed by geology and biology appalled those who confused the literal truth of "Genesis" with the basis of religion and morality. And when the theory of evolution completed the outrage of man's expulsion from the centre of the universe by denying his special creation, resistance rose to its height. The opposition subsided only to be renewed at intervals against scientific doctrines, all of which have been of unquestioned utility in their own spheres, about the unconscious mind, about the chemical basis of genetics, the functioning of the brain and nervous system, or about the influence of hormones on personality.

Yet the men of science themselves, so far as can be judged, have numbered about the same proportion of religious believers as the generality of people. Nor have they been conspicuously less well endowed with kindness or morality. Indeed, an assurance that ultimate values of goodness and beauty can never be shaken by the pursuit of truth, wherever it may lead, is perhaps the sign of a robuster faith than is shown by recoil from every new and seemingly disturbing fact.

Meanwhile, in the natural course of discovery and interpretation, and uninfluenced either way by real or supposed philosophical or theological implications, scientific ideas evolved in a direction where they largely lost again their mechanical and materialistic semblance, and acquired a curiously abstract character. Indeed, some physical principles (though not, I think, adequately understood), have even been used in the present century in support of idealistic philosophies or to provide a doubtful support for the otherwise respectable doctrine of free will.

The quantum theory added a new element, that of discontinuity to the Newtonian conception of the world. Electrical particles, the building blocks of matter, filling the universe with electromagnetic waves by their motions had offered for a time a synthesis of grand simplicity, powerful enough to create the whole technology of radio communications, and a major part of the electrical industry, yet itself destined for a revolutionary metamorphosis. Nature gradually disclosed that the invisible substratum of

PRINCIPLES OF METEORITICS

by **E. L. KRINOV**

This book contains a broad exposition of problems dealt with in meteoritics, covering the study of the material composition, structure, morphological and physical properties of meteorites, together with the study of the conditions under which meteoric bodies move through the Earth's atmosphere and in interplanetary space. **70s. net ($12.00)**

ANALYTICAL CHEMISTRY OF THE RARE EARTHS

by **R. C. VICKERY**

The first volume to be devoted specifically to the analytical problems encountered in dealing with the rare earths, it covers all phases of the problems from decomposition of the analytical sample to ultimate element determination. Particularly adaptable for graduate and undergraduate students of analytical chemistry as well as the specialist analyst. **In preparation**

A GUIDE TO MATHEMATICAL TABLES

by **A. V. LEBEDEV and R. M. FEDOROVA**

Working mathematicians and technical librarians have long felt the need for a thorough guide to the mathematical tables available in the world literature. The translation of the present compilation prepared for the Computing Centre of the U.S.S.R. Academy of Sciences, fills this need. **£5 5s. net ($15.00)**

A Guide to Mathematical Tables

SUPPLEMENT NO. 1.

by **N. M. BURUNOVA**

Since the translation of *A Guide to Mathematical Tables* by Lebedev and Fedorova was prepared for press, the U.S.S.R. Academy of Sciences has issued a supplement which brings the Guide up-to-date with respect to tables published throughout the world up to the end of 1958. An English translation of this supplement is also available from Pergamon Press. **50s. net ($9.00)**

things, electrons, particles and waves could no longer be described at all in terms applicable to the macroscopic world of the senses. Intuitive notions of space and time had been called in question by the theory of relativity; the idea of a sub-atomic particle now became expressible only in terms of an abstract mathematical equation. Electrons themselves proved subject to the peculiar rule that only so many of them could be present in one system as were absolutely distinguishable by individual values of certain numbers which prescribe their state. Separate existence and experimental distinguishability were essentially linked. It is this almost metaphysical principle which accounts for the complete system of the chemical elements, with all their rich and varied detail. Particles appearing in nuclear disintegrations at high energies, mesons and the like, possessing the character of transience and decaying into others, present to-day an enigma which will probably not be solved until radically new principles have been discovered. The mysteries of the minute world of the atomic nucleus are found in magnified reflexion in those of the stellar universe. How did the present cosmic era start? Will it be renewed? Is the so-called ultimate particle itself a cosmos of still smaller things? Is the known universe contained within a particle belonging to some higher order? Mystery and fascination have no end, the pursuit of knowledge has no limit. Three hundred years have witnessed the most colourful adventure ever undertaken. Is this too not history?

In the broader sense this story is that of the Royal Society, for its membership has known no restriction of race or nation. It has been proud to number a goodly proportion of the world's greatest men of science among its Foreign Members.

The real actors in the drama of these centuries have been individuals, often rare individuals. What then in it all has really been the role of the Royal Society as a corporate body? This question is related to that most profound of problems, the relation of the individual to the community.

The hierarchical ordering of things, which can be seen both in the inorganic world and in the organic world, makes the community of one order the individual of the next order, not only through the gradations of human society and the animal kingdom, but also in the relation of cells to tissues, electrons to atoms and atoms to crystals. An almost metaphysical principle rules communities of electrons, chemical influences co-ordinate the lives of separate cells, and, to quote a single instance from biology, some mysterious kind of transmission beautifully regulates the flight of certain flocks of birds.

The modes of communication in human societies are known; but what remains mysterious is the blend of rational and emotional influences that determines the response. The great movements of thought and even the lesser ones of whim and fashion spread from leaders. Only minorities in general exercise an independent taste and judgment or produce original thought. Yet at one time a prophet is followed and at another he cries in the wilderness. Avogadro and Mendel achieved their fame posthumously. Literary reputations wax and wane. The shrewdest are unable to predict with certainty what public response to anything will be. The propagation of an idea demands the right conjunction of unknown human factors, but even when these are propitious nothing will initiate the change save the operation of a minority small enough to defy statistical considerations. Often indeed the minority begin with a single individual who alone would be helpless; and thus the majority and the minority are held in mutual dependence.

Scientific investigation needs material ways and means, and the further knowledge advances the more lavish becomes the scale. The individual in isolation becomes, except under rare conditions, correspondingly impotent. But the community as a social and political whole cannot be expected to possess the detailed understanding to support him. Nor, to-day, with the tremendous issues at stake, can it remain indifferent. What therefore must be created to mediate between the individual and the major group is a specialized minor community large enough to command prestige and confidence, but with membership confined to those who place the claims of knowledge first. The principles which should govern the constitution of such a body are highly important.

Specialized organs of the Government are by themselves unsafe, being too exposed to the changing winds of expediency. Universities suffer from the disadvantage that on one hand a given branch of knowledge is divided and scattered among many of them and, on the other hand, that they have competing preoccupations of importance to them commensurate with that of learning.

An academy therefore is the natural body to provide for several vital things—non-commercial periodicals for the publication of discoveries, a measure of financial support for ideas still too embryonic to be of immediately obvious practical application, the mutual stimulus of association and discussion and the immaterial reward of honour for intellectual achievement. Governments may act as patrons. They can and do solicit and receive the help of learned men, they favour and encourage enterprises which they judge to be timely; but they cannot provide for men of science the intangible yet powerful encouragement which comes from acceptance and election by their peers. The academy, if it maintains high standards of unquestioned impartiality, sets the tone throughout the scientific community, and its influence is felt in every quarter. It is no rival to government organizations or to industry, and should maintain the closest connexions with them by electing into its number the leaders from both. Because men of action and men of authority esteem it an honour to be elected, the academy exerts its influence far beyond the confines of the learned world. The professional men of science hear of the needs of the State and of industry which in their turn are irrigated by the currents of scientific thought. The intercourse on terms of equality between the representatives of these different estates of the nation is like a sensitive nervous mechanism endowing the community which possess it with capacities and potentialities realizable in no other way. The subtle co-ordinating action of an academy can no more be replaced by a bureaucratic organization or a system of economic incentives and deterrents than the intricately evolved biological controls of a living organism can be replaced by crudely devised mechanical appliances.

As Nature herself takes infinite pains over the perpetuation of the species, making this indeed in most respects her first concern, so the right choice of its members is a matter demanding the most anxious care of the academy, and is perhaps the most important thing it has to do.

This, then, is the conception of the Royal Society, implicit already in the personalities of its original

leterred by any of the uncer-
nce is not incompatible with or
kind of faith. Indeed, there
inconsistency in believing that
itself one of the great instru-

ments of higher ends. However that may be, duty, expediency and the zest of living unite their voices in calling for unremitting effort, not in the certainty but in the hope and faith that knowledge may advance, mastery over environment increase, drudgery be abolished, sickness healed, the people fed and life made happier. If social and moral problems are raised they are not essentially new but part of an age-old drama, and should neither be allowed to cause despondency nor to justify obstruction or abstention. The ancient choice between good and evil is in principle unchanged by the scale or fullness of existence. Men have always had to struggle with their environment, with one another and with themselves. Not exemption from danger, hostility or temptation but the power to sustain their impact has made men what they are. The great weapons have been the things of the mind, and among the greatest of these is knowledge. While the old men dream dreams and the young men see visions we should go forward undeterred, that the dreams may become reality and the visions be fulfilled.

This commemoration is for us a great event in our history. The future is unknown. The chronicles record the actions and the thoughts of men, and if, as well may be believed, thought is a creative process, then the future is more than deeply hidden: it is uncreated. The golden promises offered by the release of nuclear energy, by the exploration of outer space, by the discoveries of genetic mechanisms may in one way or another be redeemed, but the best are yet unspoken. A great upheaval of ideas may come with a complete re-orientation of science in its relation to philosophy and to the conception of possible worlds. But we know neither the day nor the hour.

It is the duty of the Royal Society not to predict, not to legislate, but to maintain within the larger community the smaller one in which creative activity can flourish. Its members owe a multiplicity of loyalties, none of which can be fulfilled without the others: to mankind in general, to their native land and to the Royal Society itself. But that is not all, for there are communities in time as well as space. The most original minds, in some sense isolated in all contemporary groupings, find their true affinities in continuing the sequence of their predecessors, and their fulfilment only in their successors. In a measure this is true not only of genius but of all men. It is what moves us in history. It is what the honouring of this occasion means.

TRI T : DISCOVERIES IN THE CHESHIRE–SHROPSHIRE BASIN

By Sir WILLIAM PUGH, O.B.E., F.R.S.
irector, Geological Survey of Great Britain and Museum of Practical Geology

TH
B
under
Britai
by t
Rese
rocks
depo

e mile survey of the Cheshire
xtension into north Shropshire
Geological Survey of Great
s programme of work authorized
t of Scientific and Industrial
ching completion. The Triassic
concealed by thick superficial
cene sands and clays; detailed

stratigraphical knowledge was lacking of the Keuper rocks and, in particular, of the number and extent of the rock-salt beds within them. To facilitate the interpretation of the disposition of these rocks below the Pleistocene cover and to assist in the mapping of them, a scheme of shallow exploratory boreholes was utilized. A series of twenty-five boreholes, 300–1,000 ft. deep, were drilled within an area of 800 square miles in the Cheshire Basin; and one deep borehole has just been completed at a depth of 5,531 ft.

This deep borehole was undertaken to prove the succession of Keuper rocks beneath the Liassic strata exposed in the Prees outlier, which extends south-westwards from south Cheshire into Shropshire. Sited at Wilkesley (Cheshire) about five miles east of Whitchurch (Shropshire), the borehole revealed a thickness of 4,969 ft. of Keuper rocks, and a concentration of rock salt in two groups (each with subordinate marl partings) which together total 1,952 ft. in thickness. An abridged log of the borehole is set out below, using names for the newly established divisions of the Keuper:

	Thickness (ft.)	Depth (ft.)
PLEISTOCENE: sands and clays	58	58
LIASSIC: clay with limestone bands: both sub-zones of the *Psiloceras planorbis* zone are provisionally identified	460	518
RHAETIC: mudstone and black shale	44	562
TRIASSIC: Keuper		
Upper Keuper Marl: marl, 'tea-green' in top 50 ft.; gypsum at 960–70 ft.	579	1,141
Upper Keuper Saliferous Beds: rock salt with subordinate beds of marl	1,327	2,468
Middle Keuper Marl: marl with subordinate gypsum and anhydrite	1,073	3,541
Lower Keuper Saliferous Beds: rock salt with subordinate beds of marl	625	4,166
Lower Keuper Marl: marl with subordinate anhydrite	843	5,009
Sandstone, provisionally called *Upper Keuper Sandstone*	346	5,355
Siltstone, mudstone and silty sandstone, provisionally identified as *Keuper Waterstones*	176	5,531

The borehole failed to reach the base of the Keuper Beds; Permo-Triassic rocks older than the lowest bed reached are about 3,000 ft. thick in other parts of the Cheshire Basin, but not necessarily at Wilkesley.

The finding of two groups of saliferous beds in this borehole, rather than one as previously believed, has important consequences when the lateral extent of each group is delineated. The old-established salt industry of Northwich and Winsford is now known to be based on the lower group; on the other hand, the industry farther south at Sandbach and Middlewich appears to take its salt from the upper group, the lower group not yet having been exploited in that southern region.

The area occupied by the lower group from its western and northern margins to the eastern boundary fault of the Cheshire Basin is about 400 square miles and that of the upper group is about 170 square miles. The reserves of salt which could reasonably have been computed before the drilling of the Wilkesley Borehole have been at least doubled; a provisional estimate amounts to 400,000 million tons, of which more than 60 per cent is in the lower group.

The outcrops of the main divisions tabulated above will be shown on the forthcoming official geological maps of the Cheshire–Shropshire Basin. Their recognition will enable a new degree of precision to be brought to the long-term planning and execution of brine-pumping. The salt encountered in the boreholes was cored and is being systematically analysed so that details may be made available for industry.

It is interesting to record that one of the shallow boreholes near the western margin of the basin, namely, that at Old Beachin Farm, six miles south-south-east of Chester, entered barren Upper Coal Measures beneath the Pleistocene deposits enabling the mapping of an inlier of Coal Measures surrounded by Permo-Triassic rocks. The borehole was deepened to 993 ft. and a sequence comparable with the Erbistock Beds of the Wrexham Coalfield was encountered. However, workable coals, if present beneath the central parts of the Cheshire–Shropshire Basin, are likely to be at depths too great for present-day exploitation.

PERIODIC MAGNETIC FIELD FLUCTUATIONS IN THE *SCEPTRE* DISCHARGE

By Dr. N. L. ALLEN

Research Laboratory, Associated Electrical Industries, Aldermaston Court, Aldermaston, Berkshire

ALTHOUGH the discharges in *Zeta*, *Sceptre III* and *Perhapsatron* appear to be stable against gross wriggling[1–3], measurements with magnetic probes have invariably shown fluctuations of magnitude about 10–20 per cent of the average magnetic fields in the discharge and mean frequencies in the range 10^4–10^6 c.p.s.[4]. Also, some correlation has been observed between striated bands of light, termed 'bars', on rotating-mirror photographs and the magnetic fluctuations[5,6].

A possible theoretical explanation of these fluctuations has been given by Ware[7]. This has recently been extended[1] by including the Hall e.m.f. in the electron conduction equation, and it has been suggested that a hydromagnetic instability will propagate as a wave. The experiments reported here form part of a search for discernible instabilities of this type.

Experimental Arrangement

The arrangement is shown in Fig. 1. Ten small search coils, each of 120 turns of No. 44 s.w.g. copper wire, were wound at intervals of 1·25 cm. on a 4-mm. diameter 'Bakelite' rod. The assembly was enclosed in a T-shaped tubular glass envelope, with the coil leads taken out through the side tube. It was then inserted into the torus through a slit window and rotated until the common axis of the coils was parallel to the toroidal axis (neglecting the curvature of the latter over the length of the coil assembly).

The coils were positioned at radii up to 10 cm. from the centre of the toroidal tube, which had a minor diameter of 30 cm.; thus they were 5 cm. from the outside wall of the vessel at the mid-point of the coil system. The output of each coil was led to an integrator and then displayed on a multi-channel oscilloscope. Hence, correlation in time between the response of the individual coils was obtained on a single photograph.

The plasma was produced by discharging a 35,000-joule condenser bank through the primary winding of the machine. The condensers were charged to 20 kV.

Fluctuation Behaviour

Typical oscillograms obtained with this arrangement are shown in Fig. 2. The pattern of periodic 'dips' or minima in magnetic field was obtained in a region between 6 and 10 cm. from the centre of the discharge tube along radii towards the outer wall. Further probe measurements showed the existence of similar patterns at corresponding radii near the other walls of the torus. The pattern was found to be repeated in these regions in 65 out of 86 discharges examined; in the remaining 21 cases the pattern was less regular, or showed few recognizable 'humps'. The magnitude of the 'dips' varied from ~ 200 to ~ 1,000 gauss.

The time-intervals between pairs of minima varied between 25 μsec. and 100 μsec. with an average of ~ 45 μsec. for 113 cases examined. A histogram showing the frequency distribution of these intervals

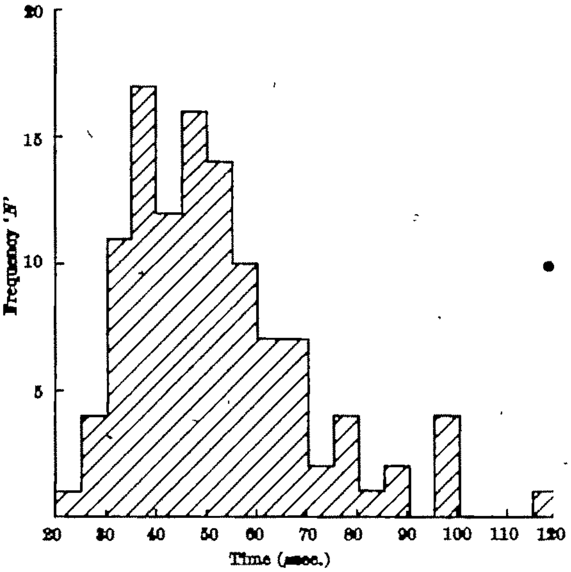

Fig. 3. Histogram showing frequency distribution of intervals between minima. No. of periods measured = 113

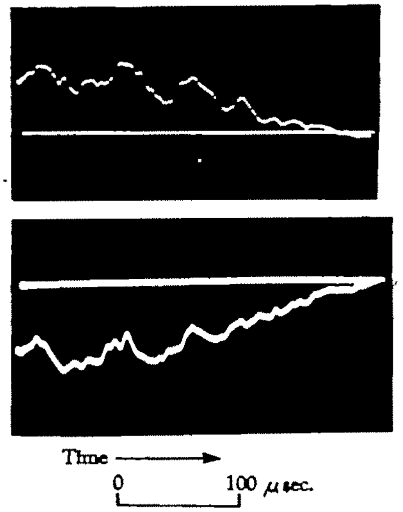

Fig. 4. Oscillograms of signals from probes placed on opposite sides of discharge. (350-μsec. sweep)
Upper, No. 4 probe, centre + 5 cm.; lower, No. 8 probe, centre − 5 cm.

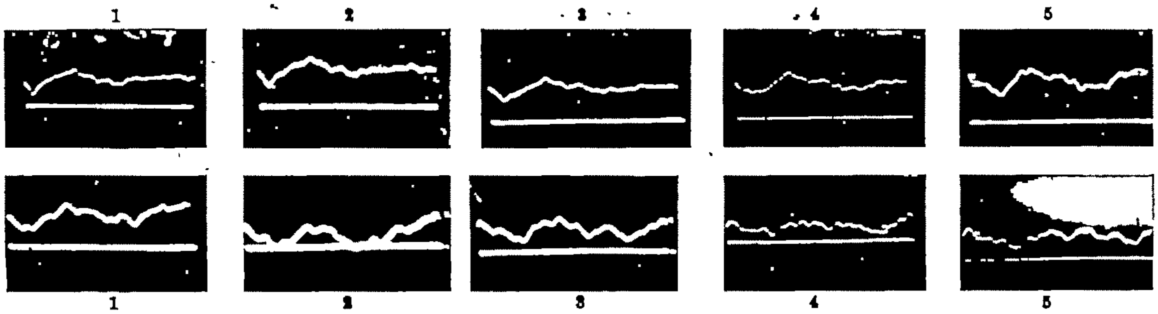

Fig. 5. Oscillograms of signals from T-probes along radii at right angles to each other. Upper row: probes 7 5 cm. from outside wall of torus; lower row: probes 7 5 cm. from upper wall of torus. Base line in each oscillogram 0–100 µsec.

is given in Fig. 3. Measurement with a travelling microscope showed an increasing time-lag between minima on No. 1 coil and those on succeeding coils up to No. 10. The average time-displacement between the end coils for 72 minima investigated in this way was 8 µsec. over the total length of 11 cm. covered by the coils, with intermediate time differences recorded by the intermediate coils.

Further investigation into the nature of the fluctuations was made by inserting a 10-channel probe across the discharge to measure axial field changes at 2·5-cm. intervals. Specimen oscillograms obtained are shown in Fig. 4, from which it is clear that an anti-phase correlation existed between peaks and dips occurring on opposite sides of the centre of the discharge.

Fig. 5 shows the relationship between the patterns obtained with T-shaped probes inserted along radii at right angles to one another in the same cross-sectional plane. The interval between peaks on the individual oscillograms (shown here on a fast sweep) was ~ 80 µsec. and the minima were displaced about 15–20 µsec. with respect to one another.

In Fig. 6, the average axial and azimuthal components of the discharge magnetic field relevant to the observations quoted above are shown. These are plotted, at peak discharge current, against tube diameter for the same initial conditions. The T-shaped probe covered the areas about *A*. They are on steeply rising parts of the B_φ component in which the resultant magnetic field 'wave-lengths' ($2\pi r\, B_\varphi/B_\theta$) vary between 26 and 175 cm.

Discussion

The time-displacement of minima along the probe assembly indicated either a velocity component of the pattern in the axial direction or a rotational motion in the azimuthal direction of a disturbance lying at some angle to the probe axis. The techniques used here could not distinguish between these two alternatives.

Taking the former possibility: a total of 72 minima was followed in their progress along the probe assembly and a spectrum of axial velocity component obtained as in the histogram of Fig. 7. The velocities showed a maximum in number at about $1\cdot5 \times 10^6$ cm./sec. A group of 17 minima existed in which a velocity was not resolvable, since they showed no significant time displacement along the probe. These are shown here as having a velocity $> 5 \times 10^6$ cm./sec. However, these minima could equally well correspond to a pattern of zero axial velocity component appearing simultaneously on all probes. The resolvable velocities (55 cases) were in the direction of positive ion drift in every case.

The alternative of azimuthal motion of an angled disturbance would indicate an angular frequency spectrum similar in profile to that of the distribution of Fig. 3, where the time axis is replaced by the reciprocal of the frequency. At a mean radius of 8 cm. from the centre, this corresponds to a mean peripheral velocity of the order $1\cdot0 \times 10^6$ cm./sec., assuming only one perturbation for each rotation.

The results are consistent with a model of a helical disturbance moving, axially or azimuthally, in the discharge. This model is supported by the observations, with probes on either side of the discharge centre, of an antiphase correlation and by the observation of a phase shift between the two probes at right angles. The results suggest the presence of an $m = 1$ type of instability. Such behaviour has been reported by other experimenters[9,10] at lower discharge currents. The present results do not depend critically on discharge current values, since the fluctuations occur over a considerable part of the pulse.

Conclusion

Strong periodic fluctuations in the axial magnetic field component suggest the existence of a helical type of instability near the discharge channel surface. The instability is moving either in the axial direction with an average velocity of $1\cdot5 \times 10^4$ cm./sec. or in the azimuthal direction with an average rotational frequency of 2×10^4 c.p.s. or could be a combination of both types of motion. Variation in the fluctuation period during the pulse-time is probably due to general movement of the discharge as a whole.

I wish to thank Messrs. H. B. Mundy and V. C. Cloke for their operation and maintenance of *Sceptre III*. I am grateful to Mr. M. J. Bolton for experimental assistance, to Dr. J. A. Wesson for discussion and assistance with measurements and to Dr. A. A. Ware for his interest and advice on the programme. Thanks are due to Dr. T. E. Allibone, director of the Research Laboratory, Associated Electrical Industries, Aldermaston Court, for permission to publish these results. The work has been supported in part by the United Kingdom Atomic Energy Authority and is in association with the Controlled Thermonuclear Research Programme of the Atomic Energy Research Establishment, Harwell.

is communication records the
rd absolute values of reflec-
ed by other workers for cali-

bration of their equipment, and for standardization of measurements. In addition, the application of a photo-conductive cadmium sulphide cell is described which has been used successfully for measurement of the spectral reflectivity of opaque minerals for different wave-lengths of incident light.

Standardization

Published reflectivity values in white light have been based on pyrite as a relative standard with which other mineral surfaces have been compared. The choice of this mineral as a standard is unsatisfactory, however, due to variation in composition and inherent anisotropy.

For calibration purposes, measurements have been made of absolute reflectivity throughout the spectrum

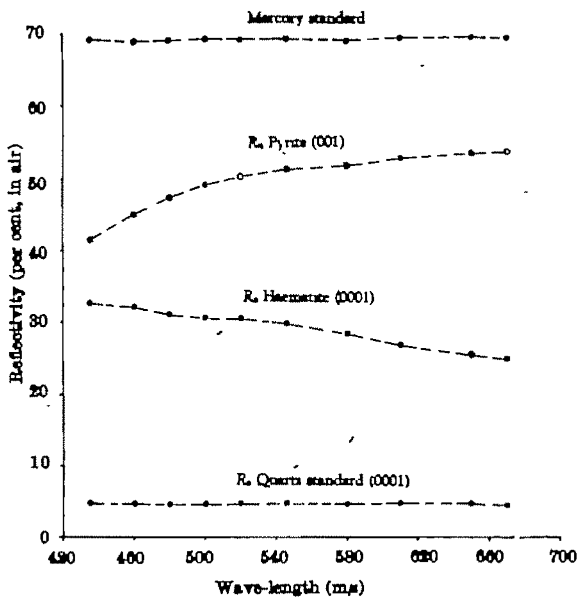

Fig. 1. Spectral reflectivity of quartz and mercury standards, and profiles of pyrite (FeS_2) and hæmatite (Fe_2O_3) as determined by the National Physical Laboratory. Computed white-light reflectivity (per cent): mercury, 69·3; pyrite, 52·7; hæmatite, 26·4; quartz, 4·5

for standard reference surfaces. The standards selected were chosen for their reproducibility and permanence, and were: (1) polished basal section of quartz, and (2) natural surface of pure mercury under a glass cover-slip (thickness 0·216 mm., refractive index 1·52). These two standards normally suffice for the photo-conductive cell which gives a linear response. As a check on the linearity of our equipment, two other surfaces were measured; these were (3) natural basal crystal face (0001) of hæmatite, Fe_2O_3, and (4) polished cube face of pyrite, FeS_2.

The reflectivities of these four surfaces, at ten points throughout the spectrum, were determined by the National Physical Laboratory (NPL Reference O.1959.34), and the results are shown in Fig. 1. The method of measurement employed for each specimen was specular reflexion from an area 0·6 mm. × 0·45 mm. for a cone of radiation, semi-angle 4°, angle of incidence 5°. From these results white-light values were computed which allow for the energy distribution of a tungsten-filament lamp run at a colour temperature of 3,050° K., and for the response profile of the cadmium sulphide cell.

Equipment

The standard values determined by the National Physical Laboratory were used for calibrating our equipment for the measurement of monochromatic and white-light reflectivity. The apparatus consists of a Mullard ORP.11, cadmium sulphide photoconductive cell fitted into the Wright ocular of a Cooke, Troughton and Simms ore-microscope. The cell is in circuit with a variable 0–100 V. d.c. energizing source, the current output being recorded on a spot galvanometer. For spectral determinations, Ilford filters of effective band-widths not exceeding 250 Å. are used; the wave-lengths of maximum response of the measuring system allowing for the spectral characteristics of light source, filters and cell are as follows: blue 470 mμ, green 520 mμ, yellow 575 mμ, orange 600 mμ, red 700 mμ. Under standard conditions, with an objective of 0·65 N.A., a 10° cone of incident light, and a stabilized 6 V. 48 w. tungsten-filament light source, the output of the cell varies between 1 μamp. and 5 m.amp. according to the surface measured and wave-length employed.

Results

To illustrate some of the characteristics of spectral profiles of anisotropic opaque minerals, three examples have been selected from the many oriented minerals which have been examined in plane-polarized light.

Fig. 2 shows the spectral profile in the two principal directions of reflectivity, R_e and R_o, in the case of covellite, CuS. At yellow wave-lengths, which approximate to white light, $R_o > R_e$, but in blue, green and red light, $R_e > R_o$ (although to the eye $R_e < R_o$). Moreover, at about 550 and 640 mμ, $R_e = R_o$, that is, the mineral is no longer bireflecting and anisotropic. This 'bireflexion reversal' has not been observed before in opaque minerals due to intensity insensitiveness, and chromatic bias of both the human eye and the conventional selenium photoelectric cell. This phenomenon of reversal is analogous to similar properties of directional refractive index in transparent minerals, based on sign of character of uniaxial or biaxial birefringence. The suggested notation for opaque minerals is 'positive bireflectance', where $R_o > R_e$, and 'negative bireflectance', where $R_e > R_o$.

In Fig. 3, a comparable type of profile is shown for umangite, Cu_3Se_2, with strong absorption at yellow wave-lengths. In this case, however, there is no reversal of bireflectance; minimum bireflectance occurs at 580 mμ. This mineral is particularly interesting since visual estimates of colour and intensity suggest opposite bireflectance at red wave-lengths. Also illustrated in Fig. 3 are the profiles of pyrrhotite, $Fe_{1-x}S$, with higher reflectivity but lower bireflectance. R_e is consistently greater than R_o (negative bireflectance), and maximum reflectivity occurs at green wave-lengths, with absorption towards the blue and red ends of the spectrum.

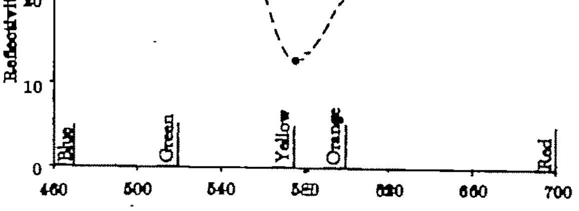

Fig. 2. Profiles of reflectivity R_e and R_o against wave-length in the principal directions of oriented sections of covellite (hexagonal CuS, Sardinia). For R_e, plane of polarization is parallel to c-axis direction; for R_o, it is normal to c-axis direction. White-light values (per cent): R_o, 24·0; R_e, 17·6. Field N, negative bireflectance with $R_e > R_o$; Field P, positive bireflectance with $R_o > R_e$; I, isotropy with $R_e = R_o$

The sta
enabled acc

usions

procedure employed has
nations to be made of the

absolute reflectivity in air of oriented polished sections of opaque ore-minerals in both monochromatic- and white-light. The spectral profiles obtained from these measurements show variation in reflectivity, bireflectance magnitude and sign. The insensitivity of the human eye to wave-length intensity coupled with its inherent colour bias cause apparent anomalies in intensity change compared with photo-conductive cell measurements. This is particularly apparent with wide band-width filters using standard comparison methods (visual micro-photometer), and with selenium photo-electric cells which respond in a manner comparable to that of the eye. The fundamental data of absolute reflectivity in white light combined with the characteristics of spectral reflectivity profiles are of great significance in the interpretation of other optical phenomena in polarized light, such as natural colour, spectral dispersion, rotation of polarization plane and conoscopic isogyre effects under crossed Nicols.

The detailed results of this study of the spectral reflectivity of about 200 oriented ore-mineral oxides, sulphides and sulphosalts, and the application of the data and technique to the systematic identification of economic minerals, are to be published in full elsewhere.

. During his six and a half

years in the British Museum he published several papers, both on the rocks of Glen Urquhart and on their metamorphism; he was especially interested in metamorphic facies boundaries, and his original contributions on the subject are worthy of note. It is a matter of regret that his unexpected death left so many of his works incomplete or unpublished; some, including a long paper on "Alkali Metasomatism and its Consequences in Glen Urquhart, Inverness-shire", will be published posthumously.

Dr. Francis was a keen field geologist, and his short career was pleasantly punctuated by three expeditions—to South Peru in 1954 and 1959, and to South Greenland in 1957. The two Peruvian expeditions (the first of which was also his honeymoon) were to study the nepheline-syenite Allincoapac massif, rising to a height of nearly 19,000 ft. in the Province of Carabaya; the purpose of the Greenland expedition was to undertake a study of the same rare rock type in a classic area and to collect specimens of other rocks. All three expeditions resulted in the production of useful topographical and geological maps and (in the case of the 1954 expedition) a paper on the general geology of the area. The Peruvian expeditions also afforded opportunities for archæological work; Dr. Francis published an account of two hitherto unrecorded pre-Columbian villages at Chichacori and Quilliquilli in the gorge of the Rio San Gaban, and he collected fine examples of artificially deformed human skulls from mummies of the period.

The little-known mountain ranges of Peru and Greenland were an even greater attraction to Dr. Francis than was the nepheline-syenite, and he made first ascents in both countries. Indeed, he was a noted climber, having been chosen to take part in another assault on Everest in the autumn of 1953 if the first assault should fail. He was a former member of the Mountaineering Clubs of both his Universities, being treasurer at Oxford, and had undertaken many Alpine climbs of the utmost severity; he sat on the committee of the Alpine Club and was secretary of the Mount Everest Foundation screening committee; his book, "Teach Yourself Mountain Climbing," is the standard work recommended by the British Mountaineering Council, and he had helped edit a guide-book to selected climbs in the Mont Blanc range.

Dr. Francis's quiet and modest manner gave no hint of those qualities which made him such an outstanding leader—initiative, loyalty, courage, perseverance and stamina. His enormous sense of fun helped him to enjoy every aspect of his happy and varied life. He will be greatly missed, both as a scientist and as a friend.

He was married to Gillian Hemens in 1954, and leaves also a son and infant daughter.

A. J. CHARIG

Dr. H. F. Barnes

DR. H. F. BARNES, senior principal scientific officer in the Entomology Department at Rothamsted Experimental Station, died suddenly on February 5, at the early age of fifty-seven. He was at the height of his scientific output, and still full of activity and ideas for the future.

Educated at Bedford School, he obtained his B.A. and M.A. at Oxford, and Ph.D. at London. His work was largely based on the group of Diptera known as gall-midges or Cecidomyidae; but his approach was a very wide one, including their economic status and natural control; their geographical and food-plant range; systematics, including a very close study of biological species and races; their parasites and phenology; and particularly the accurate study of population changes by field measurements. At Rothamsted he assessed the population-levels of two species each year for more than twenty-five years, providing a wonderful basis for the discussion of insect fluctuations and their causes. His work on the group—which covered the whole world—was published in more than fifty papers and seven (out of a contemplated eight) volumes of his "Gall Midges of Economic Importance".

His collection, now in the British Museum (Natural History), was unique in its coverage of the economic species of the whole world and in its long series of hundreds of specimens from different localities and bred from different host-plants. From this material, Barnes was able to solve many questions as to the identity of insects causing similar damage in different countries.

For some years, during the War and after, Barnes took up the study of injurious slugs in Britain, and once more tackled the question of accurate assessment of population and population changes in the field.

He was zoological secretary of the Association of Applied Biologists during 1939–44 and treasurer during 1947–60. He also edited the *Bedford Naturalist* from 1952 until his death. He paid a number of visits abroad, where his reputation was high owing to the world-wide outlook on every problem that he tackled.

On the personal side, I may add that I worked side by side with him at Rothamsted for more than twenty years, and found him a good friend, a stimulating companion and a very loyal colleague.

C. B. WILLIAMS

NEWS and VIEWS

Royal Navy Hydrographic Department: Rear Admiral K. St. B. Collins, C.B., O.B.E.

ON July 7, Rear Admiral K. St. B. Collins was succeeded by Rear Admiral E. G. Irving as hydrographer of the Navy. Admiral Collins has held office for five years in a difficult period of retrenchment and staff reduction which have been imposed upon the Hydrographic Department in common with other branches of the Royal Navy. But despite these reductions, the Department, under Admiral Collins's direction, met, during these years, increased demands for charts from the merchant navies of the world. A new record was achieved in 1957, when 1,404,450 charts were sold, and only a slight reduction in sales, attributable to a world shipping recession, has occurred since that time. As a direct result of his encouragement, Admiral Collins has seen a steadily increasing inflow of reliable oceanic sounding data from many sources so that the world-wide series of oceanic plotting sheets, introduced by his predecessor, Admiral Day, is now increasingly referred to by oceanographers and those interested in the morphology of the ocean floor. These sheets are regularly supplied to the International Hydrographic Bureau for use in the compilation of the General Bathymetric Chart of the Oceans. Admiral Collins has served as chairman of the World Geomagnetic Survey Panel and the Physical Oceanography Sub-committee of the National Committee for Geodesy and Geophysics. He was a member of the National Oceanographic Council and a member of the Executive Committee of the National Institute of Oceanography. He served on the National Committee for the International Geophysical Year. During his period of office, he was able to grant a considerable number of facilities to scientists in Her Majesty's surveying ships, this being in the best traditions of the Surveying Service, while oceanographic tasks for the National Institute of Oceanography, the Department of Geodesy and Geophysics, Cambridge, and the British Museum (Natural History) and other establishments have been increasingly included in Commanding Officers' Hydrographic Instructions. The introduction of electronic aids for fixing the ship while sounding and for base measurement of triangulation onshore have been generally introduced into the Surveying Service by Admiral Collins, and it is for his vigour in introducing these systems that he will be remembered by surveying officers. He was, however, always quick to point out the gross errors that may be introduced into electronic systems by carelessness and insisted that they should be subject to frequent check by well-tried visual methods.

and Steel Institute

Iron and Steel Institute has
medal award, to be known
as "The Medal of The Iron and Steel Institute". This Medal is to be presented on special occasions to societies which have, in the opinion of the Council of the Institute, rendered exceptional service to science or industry over a lengthy period. The first award of the Medal is to be made to the Royal Society, in recognition of its unique service to science over a period of three hundred years. The Medal was presented by the Hon. R. G. Lyttelton, past-president of the Iron and Steel Institute, at the Tercentenary Celebrations of the Royal Society on July 18.

Advisory Council for Research and Development in Fuel and Power

IT is announced that the Scientific Advisory Council to the Minister of Power has been reconstituted and its terms of reference amended so as to emphasize that its advisory functions cover all aspects of research and development concerned with fuel and power from the laboratory to industrial application. In order to ensure the co-ordination of the advice which the Minister receives on research and development matters, the Council will take over the functions of the Minister's Fuel Efficiency Advisory Committee. This Committee is accordingly being wound up and the Council is being invited to appoint a standing Committee on Fuel Technology. The members of the Advisory Council on Research and Development are as follows: *Chairman*, Sir Alexander Fleck; *Deputy Chairman*, Captain (E) W. Gregson; *Members*, Lieut.-Colonel S. J. M. Auld (oil industry consultant), Dr. C. M. Cawley (chief scientist, Ministry of Power), Mr. T. B. Clark (Imperial Chemical Industries, Ltd.), Sir Josiah Eccles (deputy chairman, Electricity Council), Mr. W. K. Hutchison (deputy chairman, Gas Council), Dr. W. A. Macfarlane (managing director, National Industrial Fuel Efficiency Service), Sir Harry Melville (secretary, Department of Scientific and Industrial Research), Mr. L. Rotherham (member for research, Central Electricity Generating Board), Prof. M. W. Thring (University of Sheffield), Dr. F. A. Vick (deputy director, Atomic Energy Research Establishment, Harwell), Mr. A. H. A. Wynn (scientific member, National Coal Board); *Assessors*, Mr. P. Chantler (economic adviser, Ministry of Power), Dr. E. Lee (director, Stations and Industry Divisions, Department of Scientific and Industrial Research), Mr. H. T. Ramsay (director, Safety in Mines Research Establishment, Ministry of Power); *Secretariat*, Dr. E. N. Eden and Mr. E. W. Prior (Ministry of Power).

The National Council for Technological Awards

THE report of the National Council for Technological Awards for the period April 1959–March 1960 records the agreement of the Minister of Education to an amendment of its constitution so as to ensure the inclusion of principals of colleges of advanced technology, and three such principals—Dr. E. C. Edwards, Dr. J. S. Tait and Dr. P. F. R. Venables—have been nominated by the Minister as members (Pp. 26. London: National Council for Technological Awards, 1960). During the year, thirteen courses at six colleges were recognized as leading to the Diploma in Technology, five courses rejected and seven courses referred back. Since September 1956, 100 courses in all, at twenty-three colleges, have been recognized as leading to the Diploma, and of these eighty-nine have commenced, and the number of students attending the first year of such courses is now 1,558, including forty women students: 129 students gained the Diploma during the year. The Council has set up a Panel, under Sir Walter C. Puckey as chairman, to advise them on industrial training for the Diploma in Technology and the collective responsibilities of the firm and the college in this field. A memorandum setting forth the requirements of the Council, the responsibility of the firm and the responsibility of the college has been issued for the guidance of firms and colleges (Memorandum on the Industrial Training of Students following Courses recognized as leading to the Diploma in Technology. Pp. 11). At the conclusion of a course the firm will be responsible for assessing the extent to which the student has benefitted from his industrial training and for certifying to the college that he has completed his training satisfactorily. The college is responsible for certifying to the Council, in the light of this certification, that the student has completed satisfactorily a course of industrial training in accordance with the Council's requirements, as well as for making appropriate arrangements for collaborating with firms and ensuring that where the training is received at more than one firm the complete scheme of training followed complies with the statement of the broad nature and sequence of training required for the particular course. The Council has also issued a List of ninety-five courses at twenty-three colleges which are now recognized as leading to the Diploma in Technology (List No. 11. Diploma in Technology. Pp. 5).

Polar Research in the U.S.S.R.

The first Arctic drift expedition, led by I. D. Papanin, took place in 1937–38. Six expeditions of the same type followed, and since 1954 drifting Arctic stations are a constant feature of the regular survey. Recent progress of this work is reviewed by P. A. Gordienko (*Priroda*, 6, 35; 1959), while recent progress in the oceanography studies in the Arctic is described by A. F. Treshnikov (*Priroda*, 2, 25; 1960), especially all the work done on the distribution of currents, temperature, chemistry and biology of the Arctic Ocean as influenced by the submarine Lomonosov ridge. The work of the Antarctic expedition of the Academy of Sciences is constantly under review. K. A. Brodsky, K. K. Markov and V. I. Shilnikov (*Priroda*, 7, 19; 1959) give a summary account of the geographical zonality at high latitudes of the southern hemisphere. It is provided with a map in colour and several sections illustrating the distribution of temperature and salinity in the different parts of the ocean. The glacial cover of the Antarctic, as determined by the seismic survey, is discussed by Y. M. Model and A. V. Nudelman (*Priroda*, 11, 93; 1959), who have assembled together the results of the various national expeditions. They give an outline structural map of the Antarctic continent with indications of the probable mountain ranges and rift troughs.

International Bird Preservation

In its annual report for 1959 the British Section of the International Council for Bird Preservation announces the additions of the U.S.S.R., Portugal and Malaya to the national sections of the Council, bringing the total number of subscribing countries to forty-eight. Another important event has been the setting up of a special sub-committee of the British Trust for Ornithology to investigate the injurious effects of pesticides on wild life. Reference is made to the mass destruction of small birds in Italy to be served up as savoury dishes to tourists. Individual tourists, it is claimed, can do much to eliminate this practice by expressing their displeasure and disgust when they see small birds served in restaurants. The Indonesian authorities are trying to control the clandestine traffic of birds of paradise plumes between New Guinea and Singapore. These beautiful birds face the threat of destruction while their plumes are in demand for purposes of personal adornment. The report also points out that, while Lord Ilchester was one of the first to raise the question of oil pollution of the sea in the House of Lords nearly forty years ago, the evil still persists. When the International Convention for the Prevention of the Pollution of the Sea by Oil came into force on July 26, 1958, eleven maritime countries had ratified; on March 2, 1959, Finland ratified, thus bringing the total up to twelve. It has since been announced that the United States has also accepted the International Convention, though with certain technical reservations. The report of the British Section may be obtained from the International Council for Bird Preservation, c/o British Museum (Natural History), Cromwell Road, London, S.W.7, price 3*s*.

South Australia Museum

The annual report for 1958–59 of the South Australian Museum in commenting on the field work accomplished describes the search for Tertiary mammalian records in the Lake Eyre Basin (Pp. 15. Adelaide: Government Printer, 1960). This was a joint expedition with the University of California and enabled a clearer picture to be obtained of the stratigraphy of the region than had been possible before. Several other expeditions were arranged, and such activities should be an incentive to museums in Great Britain to conduct similar work in spite of the financial position. The Cave Exploration Group has undertaken further work at the Specimen Cave, Naracoorte. An underwater research group has also been formed and is being fostered by the museum. Its activities—in which many members of the staff take part—has added many specimens to the marine collections.

Classification of Pharmaceutical Preparations

Because of the toxic or dangerous nature of many pharmaceutical preparations, special regulations are necessary to prevent risks of poisoning and other risks to which they may give rise. Trade in pharmaceutical preparations must be controlled, and for this purpose a classification of such preparations must be established. Twenty years ago it was relatively easy to establish such a classification, but since then hundreds of new preparations have been put on the market, and earlier systems of classification do not fully satisfy present requirements. The principles which inspired or still inspire such classifications vary from country to country. These regulations contain two common elements: certain pharmaceutical preparations may be supplied only against a medical prescription; and some may be sold only by pharmacists. Despite these common factors, the regulations of different countries vary considerably so that any possible attempt at obtaining uniformity is beset with difficulties. Televisio s

THE f television services of Great
Britain i constant review by the Postmaster-General and his Television Advisory Committee. The latter in turn has a Technical Sub-Committee, which has been asked to consider the relative merits of the 405-line transmission used in Britain, and the 625-line system now in general use in Europe. Consideration has also been given to the possibilities of colour television and to the best direction in which to develop the higher frequency bands IV and V when these are available. To assist the sub-committee in its task, a working party was established to organize and conduct field trials designed to give technical data on the performance of some of the systems concerned. These trials were carried out during 1957–58, and in view of the importance of the scientific and technical results obtained, these are now made generally available in a report published by the British Broadcasting Corporation (Television Field Trials of 405-Line and 625-Line Systems in the UHF and VHF Bands, 1957–1958. Pp. 152. London : British Broadcasting Corporation, 1960. 20s.).

The first part of the report gives the results of field trials of 405-line television in bands I and V, using frequencies of about 45 and 650 Mc./sec., respectively. These show that the service area is more limited at the higher frequency, and is subject to greater irregularity in hilly terrain. It is therefore evident that a greater number of transmitters would be required for a band V service than is at present used in band I. In the second series of trials described in Part 2 of the report, a comparison was made between 405-line television in band I with 625-lines in band V. In areas where adequate field strength prevailed, the band V pictures were slightly better. The appendixes to the report contain a large number of diagrams illustrating in considerable detail the various features, subjective as well as objective, of the results obtained in these extensive trials.

New British Analogue Computer

IN a recent issue of *Nature* (186, 201 ; 1960) the first British digital-analogue computer, the *Corsair*, was described. Now a second machine of digital-analogue type has been introduced by the Redifon Company. The new Redifon machine differs completely in concept from the *Corsair*, since the actual calculations are performed exclusively by analogue techniques. Even multiplication, which is notoriously unsatisfactory using an analogue device, is treated in this way. The digital part of the machine lies in its input–output device which makes use of magnetic tape upon which information is recorded by a machine of standard keyboard and through which information can be obtained via a typing device of the sort used in adding machines. The magnetic tape store which is associated with the *Radic* system, as it is called, has a number of novel features, including the interesting one that the magnetic tape is perforated with sprocket holes and apparently moves discontinuously. This technique makes such operations as the serial correlation of recorded data particularly easy, and will undoubtedly result in the *Radic* computer filling a niche which previous analogue computers have failed to do.

Interstellar Extinction and Polarization

THE study of the particles in interstellar space is important for two reasons. First, interstellar dust produces absorption of light, and makes difficulties for astronomical distance determination. Secondly, the discovery of interstellar polarization by Hall and Hiltner indicated the existence of a general galactic magnetic field, and one would like to determine the strength and direction of this field. H. C. van de Hulst studied the scattering of light by homogeneous spheres, and from the observed extinction concluded that the interstellar grains are dielectric, and are about 1μ in size. The grains must be asymmetric in shape to produce interstellar polarization, and the relation between the observed polarization and extinction will depend on the shape of the particles. It would be an improvement if the theory could be based on scattering by long cylinders. R. Wilson (*Mon. Not. Roy. Astron. Soc.*, 120, 51; 1960) has recently published an approximate solution of this case for refractive index near unity. Extinction curves have been computed for different degrees of polarization; it is predicted that the colour excess per unit mass and the ratio of the total to selective extinction will both depend on the polarizability. The predictions are compared with observation, and confirmation is obtained of the existence of a general galactic magnetic field aligning the interstellar grains by a mechanism of paramagnetic relaxation as proposed by L. Davis and H. L. Greenstein. The new expression for the ratio of total to selective absorption may lead to substantial revisions in the distances of some of the more distant stars.

Abundance of Marine Plankton

An unusual and worthwhile statistical study of the abundance of marine plankton has been made by R. M. Cassie in the March issue of the *New Zealand Journal of Science*. He has analysed the results from a transect of sixty stations starting in the open sea and passing through a zone of mixed water into harbour water. Partial and multiple regressions were calculated, relating the abundance of each species to that of five other species, to temperature and to salinity. The regressions accounted for much of the variation, but the residuals were not randomly distributed, so that the interpretation of the results is necessarily inconclusive. It is inevitable that the results of one day's sampling should be suggestive rather than informative, but the technique which Cassie has described is likely to prove most useful in the quantitative study of the relationships of animals and plants to each other and to their physical and chemical environment.

Pelagic Polychaetes of the South Atlantic

The samples collected since 1925 during the Discovery Investigations of the southern oceans continue to provide fruitful material for studies of systematics and zoogeography. In Discovery Reports (30, April 1960), Mr. N. Tebble has made a study of the pelagic polychaetes. A systematic account is given of the twenty-nine species recorded in the South Atlantic; this is followed by a description of the distribution of these species in relation to the environment. Only three species were found to be endemic to the Antarctic zone, while sixteen were found only to the north of the Sub-Tropical Convergence. Of the remaining species, four were cosmopolitan in distribution. The results conform to the usual pattern of plankton distribution in the South Atlantic with a few species occurring in large numbers in the Antarctic zone and a great variety of species forming a small standing crop in the sub-tropical and tropical zones.

Research Committee on Archæological Field Experiments

Excavators have long had to deal with the setting up of ditches, soil creep and other similar phenomena. They also have to notice the activities of worms which have frequently considerably altered the original soil structure. Too little has been known about these matters, and at the Glasgow meeting of the British Association in 1958 a discussion on the natural processes leading to the burial of archæological remains was inaugurated. This led to the formation of a Research Committee which made preliminary investigations. The idea, now, is to start in a chalk down environment and to make there a simple earthwork which can be kept under review for a long period of time. Later similar projects in sandy and clayey situations will be undertaken as funds allow. The first site selected is near the summit of Overton Down near Marlborough, on the Fyfield Down reserve of the Nature Conservancy. After the earthwork is made a careful study at regular intervals will be undertaken so that more exact data relating to the infilling of the ditch and the weathering of different kinds of objects can be obtained. Only those with permits will be allowed on the site and no cars will be permitted anywhere near it. It is hoped in this way to learn something of the mechanics of these well-known phenomena in a chalk down milieu.

U.S. Gas Chromatography Research Center

A new Gas Chromatography Research Center, the first of its kind, has been established by the Barber-Colman Co., at Houston, Texas. The primary function of the Center will be new instrument development and evaluation of component parts and accessories. This will include the development of laboratory chromatographs, portable chromatographs, process monitors and custom instruments, as well as refinement of argon and flame ionization detectors, sample injection devices and other accessory designs. Further information can be obtained from Ad. Auriema, Inc., 85 Broad Street, New York 4, N.Y.

Analytical Chemistry and Applied Spectroscopy at Pittsburgh

The twelfth Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy will be held at the Penn-Sheraton Hotel in Pittsburgh, Pennsylvania, during February 27–March 3, 1961. About 150 papers will be presented on all phases of analytical chemistry and spectroscopy. A symposium entitled "New Frontiers in Optics and Spectroscopy" will be sponsored jointly by the Pittsburgh Conference and the Optical Society of America. Original papers are invited on all phases of analytical chemistry, spectroscopy, and nucleonics applied to analysis. The final date for receipt of abstracts is October 15. Further information can be obtained from Dr. William F. Harris, Research Laboratories, Westinghouse Electric Corporation, Pittsburgh 35, Pennsylvania.

Allen (lecturer in civil engineering), C. H. B. Mee (assistant lecturer in physics).

Announcements

Prof. Alexander Robertson, emeritus professor of organic chemistry in the University of Liverpool, has been appointed a member of the Agricultural Research Council arising from the appointment of Prof. E. G. Cox as secretary to the Council.

Dr. T. F. West has been appointed editor of *Chemistry and Industry*, the weekly journal of the Society of Chemical Industry. Dr. West is at present editor of *Pyrethrum Post* and the author of the standard work on DDT, of a treatise on chemical control of insects and of a book on synthetic perfumes. He was for some years a director of Drug Houses of Australia, Ltd.

Mr. G. D. Speake has been appointed deputy chief of research at Marconi's Research and Development Laboratories, Great Baddow, near Chelmsford, Essex. Mr. Speake joined Marconi's Wireless Telegraph Co., Ltd., in 1950, when he was engaged in radar systems research. In 1954 he was appointed chief of the Vacuum Physics Section of the Research Division, and two years later he became chief of the Microwave Physics Section.

The Research Study Group, which was appointed to study the need for further research into the effects of the use of toxic chemicals in agriculture and food storage, has begun its inquiries. The Group is prepared to receive written evidence of views on the subject of the inquiry from persons or organizations. Written evidence should be addressed to the secretary of the Group, Dr. E. J. Miller, Plant Pathology Laboratory, Hatching Green, Harpenden, Herts.

The British Society of Rheology will be holding a meeting on "Rheology of Polymers" at Swansea during September 8–10. Further information can be obtained from Dr. M. F. Culpin, 8 The Broadway, Pontypool, South Wales.

The 1960 International Conference on Nuclear Structure will be held at Kingston, Ontario, Canada, during August 29–September 3. Further information can be obtained from R. L. Graham, Atomic Energy of Canada, Ltd., Chalk River, Ontario.

The first International Symposium on "Cori' Ester and Phosphorylated Glucides" will be held at the Museo della Scienza e della Tecnica, Milan, during September 16–18. Further information can be obtained from the Secretary of the organizing committee of the Symposium, Via Modica 6, Milan.

An International Symposium on "Data Transmission" is being sponsored by the Benelux Section of the Institute of Radio Engineers in co-operation with Het Nederlands Radiogenootschap and the Institute of Radio Engineers Group on Communications Systems, at the Technische Hogeschool during September 19–21. Further information can be obtained from B. B. Barrow, secretary of the Benelux Section, Institute of Radio Engineers, Postbus 174, Den Haag, Nederland.

THE ROYAL SOCIETY: APPOINTMENTS AND AWARDS

THE Council of the Royal Society has appointed Dr. J. Seed, of the Department of Radiotherapeutics, University of Cambridge, to a Foulerton Gift research fellowship as from October 1, to enable him to carry out an investigation of the control mechanisms of nucleic acid and protein synthesis in normal and tumour cells, with particular reference to the actions of ionizing radiations in radiotherapy at the Department of Radiotherapeutics, University of Cambridge. The Council has also appointed Dr. D. T. Edmonds, of the Clarendon Laboratory, University of Oxford, to a Mackinnon research studentship as from October 1, to enable him to carry out magnetic investigation below 1° K. in large magnetic fields at the Clarendon Laboratory, Oxford.

The Committee representing the Royal Society and the Armourers and Brasiers' Company has appointed Dr. J. H. Brunton, of the Laboratory for the Physics and Chemistry of Solids, Cavendish Laboratory, Cambridge, to the Armourers and Brasiers' research fellowship as from October 1, to work on deformation characteristics of base metals at very high rates of strain, at the Laboratory for the Physics and Chemistry of Solids, Cavendish Laboratory, Cambridge.

Awards under the Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme have been made to the following: Dr. S. M. Bromfield, of the division of plant industry of the Commonwealth Scientific and Industrial Research Organization, Canberra, to assist him in visiting the Macaulay Institute for Soil Research, Aberdeenshire, for ten months from October, in order to develop his studies of processes affecting the availability of phosphorus to plants; Dr. J. A. Friend, senior lecturer in physical chemistry, University of Tasmania, to assist him in visiting the University of Reading for a year from January 1961, to enable him to study experimental techniques for the precise measurement of heats of mixing; Prof. I. Lauder, associate professor of chemistry, University of Queensland, to enable him to study 'ion-molecule' reactions by mass spectrometry at the University of Leeds, for six months from October 1960; Mr. W. V. Lewis, university lecturer in geography, Cambridge, to assist him to visit the Arctic Institute of North America, Montreal, for five months from April 1961 in order to study 'permafrost' areas, and areas once covered by large continental glaciers; Prof. H. McLennan, associate professor of physiology, University of British Columbia, to enable him to extend to invertebrate material, his studies on the chromatographic characteristics of an inhibitory principle present in mammalian brain, at University College, London, during June–July; Prof. H. B. Rycroft, director of the National Botanic Gardens of South Africa and Harold Pearson professor of botany in the University of Cape Town, to assist him in completion of study of the genus *Protea* at the Royal Botanic Gardens, Kew, and elsewhere in the United Kingdom, for six months from July.

Awards of grants by the Paul Instrument Fund Committee have been made as follows: £1,000, in supplement of a previous grant to Prof. J. D. McGee, professor of instrument technology, Imperial College of Science and Technology, London, for the construction of a television system for X-ray image intensification; £500, in supplement of a previous grant, to Dr. H. Motz, Donald Pollock reader in engineering science, University of Oxford, for the construction of a linear accelerator working at 1·6 cm. (*J*-band); £3,230, in supplement of a previous grant, to Dr. P. M. B. Walker, Royal Society research fellow, department of zoology, Ashworth Laboratory, University of Edinburgh, for the construction of a high-speed integrating microspectrophotometer, to facilitate the analysis of biological cells or liquid droplets of the order of 10^3 cubic microns volume.

AUSTRALIAN BREAD RESEARCH INSTITUTE LABORATORIES

DR. D. A. CAMERON, Minister for Health and Minister-in-Charge of the Commonwealth Scientific and Industrial Research Organization, Australia, opened the new laboratories of the Bread Research Institute at North Ryde, a suburb of Sydney, on May 16. Dr. Cameron said that it was good to see such an excellent relationship between the bread manufacturers, who had started the Institute, and the Government which contributed to its costs through the Commonwealth Scientific and Industrial Research Organization. Mr. W. Sloan, president of the Council of the Institute, remarked that the occasion was being attended by bakers from every State in Australia and from New Zealand.

The new Institute comprises laboratories covering some 14,000 sq. ft., on a three-acre site at North Ryde which was made available by the Organization. The total cost of the building was about £75,000 of which £30,000 was contributed by the Organization. During the past thirteen years the Institute has been housed in laboratories in Pacific Highway, North Sydney, which it has now outgrown. The new site will allow room for expansion, and has the advantage of being in close proximity to the laboratories of the Organization's Division of Food Preservation and Transport, now under construction.

The Bread Research Institute was established in New South Wales in 1947 following the Kinsella inquiry into the bread industry. The noted British cereal chemist, Dr. D. W. Kent-Jones, went to Australia in 1947 to advise on the establishment of the Institute. In 1950, it was recognized by the Commonwealth Scientific and Industrial Organization as an industrial research association, and now receives an annual grant from the Organization, related to its industrial income. This year the grant will be about £15,000.

With funds made available from the Wheat Industry Research Council, the Organization has recently established a small Wheat Research Unit for bio-

o bakeries throughout the
lt up an important pro-
search in various aspects
, the properties of doughs

and other subjects. This work has been done in close association with the Organization, the State Departments of Agriculture and some of the universities.

The Institute's influence now extends strongly to the flour milling industry, where its work has been largely responsible for the establishment of standards of flour quality. This has been important to the bread industry, which is thus enabled to insist on definite quality specifications for the flour it buys and has been particularly important for building up the export trade in wheat and flour. The Department of Trade and the Australian Wheat Board have called extensively on the services of the Institute in this connexion, and officers of the Institute have visited Japan and other countries in the East and Middle East to advise on the use of Australian wheats.

use range from 100 to 10,000
the cells are temperature

In the radiation chemistry field, investigations have been concentrated on such chain processes as polymerization, oxidation and halogenation. The effects of radiation on catalysts are also being studied. In the food and medical applications section, the use of radiation for sterilization of equipment is giving encouraging results, particularly in expanding the use of plastic materials which are unsuitable for heat sterilization. A study is being made on the use of radiation for the control of *Salmonella* in frozen eggs, desiccated coconut, and imported cattle feed with a high protein content. The plant genetics section has been studying the external factors which influence the radio-sensitivity of plants and the conditions under which radiation can be used to break down the interspecific incompatibility.

The Laboratories have a small animal house for testing food and pharmaceuticals for possible toxicity, glass houses and trial beds for the plant genetics work, and constant temperature rooms for insect culture.

To gain experience at the pilot stage of projects, and to allow manufacturers to carry out extensive trials, a package irradiation plant has been built in conjunction with the Owen Organization and is at present undergoing proving trials. The plant permits the automatic handling of standard packages (14 × 12 × 9 in.) through an irradiation field providing a dose of 10,000 rads to 5 megarads, according to the rate of traverse. The capacity of the plant is about 100 cu. ft. a day at a sterilizing dose of 2·5 megarads, and larger quantities at lower total doses. The plant is initially loaded with 150,000 curies of cobalt-60 and the cost of giving 1 cu. ft. of material a dose of 2·5 megarads is about 15*s*. This cost will be considerably reduced in plants designed for a special purpose. It is planned to rent four-fifths of the capacity of this plant to industrial concerns, and although it is not yet in operation its capacity has already been oversubscribed.

The Laboratory also operates an irradiation pond at Harwell. This uses the high gamma flux available from the spent fuel elements from the *Dido* and *Pluto* research reactors. It consists essentially of a water pond 20 ft. deep with facilities for mounting the freshly discharged fuel elements in a lattice containing a number of irradiation positions. The material to be irradiated is placed in watertight cylinders (3¾ or 7¼ in. diam. and 30 or 48 in. long) which are then lowered through the water shield to the irradiation position. The pond usually contains more than a megacurie of fuel element activity and will give up to 4 megarads/hr. in the small irradiation cans. The present charges for irradiation in this unit work out at about 10s. per megarad to a cubic foot of material.

In addition to the cobalt and fuel element sources, there is a 4-MeV. linear accelerator with a 2-kW. electron beam output. It is used principally for treating small samples to high dose-levels of the order of 10^8 rads and also to study dose-rate effects. It gives dose-rates a hundred times higher than those available from the gamma cells.

The Division has medium-level and tracer-level chemical laboratories. The fields covered are wide and include the incorporation of isotopes in colloids for medical studies, improved methods of synthesis of labelled compounds, the use of autoradiography as an analytical tool in metallurgy, and the operation of an activation analysis service for other laboratories.

In the physics laboratory a section works in close collaboration with the National Physical Laboratory and other national laboratories on the absolute measurement of radioactivity. It has established standards of radioactivity and issues standards for many isotopes not yet covered by the standards service of the Radiochemical Centre. The work on instruments and radiation detection is largely directed towards widening the fields of application of gauges using radioactive sources and increasing the sensitivity and discriminating powers of detectors so that tracer uses of isotopes can be extended without increasing the quantity of isotope used.

An essential feature of the work of the Research Laboratory is to discover those industrial processes and fields of industrial and academic research where advantages can be gained by the introduction of instruments or techniques using radioactive materials. An experimental and advisory service is operated which will visit firms and discuss general and particular problems, and on a payment basis will make special investigations either on the firm's premises or back in the laboratories. To further this objective, exchange visits are made with the research associations of many trades, and the Department of Scientific and Industrial Research has attached a small group which uses the facilities of the laboratories and acts as a further contact with research and industry.

For a fixed capitation fee, firms can attach a scientist to the laboratory to work on a problem of either general or commercial interest. In this way a satisfactory blending of the skills of the firm in its own field with the facilities and experience of the Laboratory is achieved.

No outline of the facilities of the Laboratory would be complete without mention of the Isotope School. It was first set up at Harwell in 1951 to give basic training in the uses of radioisotopes in research, industry, and medicine. It is open to students from all countries, and provides a basic four-weeks' course several times a year, together with a number of courses on specialized subjects such as medical applications, radiological protection and autoradiography.

PROTECTION AGAINST TIDAL FLOODING IN LONDON

MEMORIES of the effects on the east coast of Britain of the disastrous storm surge of January 31–February 1, 1953, are beginning to dim. A Government report[1], which has recently been published, is therefore a timely reminder that in the vitally important London area there is no justification for complacency concerning the present degree of protection against tidal flooding.

It is true that in 1953 the low-lying areas of London escaped flooding, but the water lapped the top of the defences at many points so that the margin of safety must have been very small. Thus the question might well be asked as to how it is that seven years afterwards the defences of London are still virtually the same, whereas at almost all other vulnerable points on the east coast of Britain they have been greatly strengthened. As will be seen, the explanation lies in the complexity of the problem and the high capital cost of a solution.

In 1953 the maximum level of the surge-cum-tide at London Bridge was 6 ft. above predicted high water. When considering the possibility of a future even higher maximum level, there are four significant features of the 1953 event which should be borne in mind: (*a*) the river discharge was low—only 2,600 cu. ft./sec.; (*b*) the normal tide on which the surge was superimposed was a spring tide, but not a particularly high one; (*c*) the peak of the surge did not coincide with the time of predicted high water, but preceded it by about 2 hr.; (*d*) considerable breaching and overspill into low-lying areas occurred farther down the estuary.

Any of these features could have been more adverse, in addition to which the magnitude of the surge itself might have been slightly greater. In order to investigate these possibilities, tests were carried out on a hydraulic model[2] of the Thames estuary. It was deduced that a major river flood of 20,000 cu. ft./sec. would have raised the 1953 level by 6 in.; also that an increase of 1·5 ft. in the surge height at Southend (or a correspondingly less favourable phasing with tide) would have added about 1·7 ft. at London Bridge, while a 3 ft. increase would have added about 3 ft. at the same point. The relief due to storage in low-lying areas was shown to be quite small—not more than 3 in. Owing to raising of the banks this should be discounted in the future.

Thus it appears that a surge 1·5 ft. higher, coinciding with a freshwater flood, would raise water-levels by about 2·7 ft. above those of 1953. If the extreme, though exceedingly remote, case be considered of the highest possible surge coinciding with a peak spring tide and a freshwater flood, then the resultant water-levels might be expected to be about 6 ft. above 1953.

be in the fully raised position. When closure was necessary, the bridges would be lowered to just above flood-level and the hinged gates then swung downwards to come to rest in the vertical position against the concrete sill at the bed of the river. A somewhat similar, but much smaller barrier, has recently been constructed on the River IJssel, Holland. Experience gained in its operation should prove invaluable.

The swing bridge type would have a similar foundation design to that just described, but the three central piers would have a much greater length in the direction of flow. Three lattice girder swing spans would be pivoted on the piers and these would carry the hinged gates in the same manner as in the first type. On closure, the spans would swing on their pivots, meeting in the centre of the two main waterways.

The lifting type would be better for navigation, owing to the shorter piers, whereas the swing bridge type would be easier to maintain. The estimated cost of the swing bridge type is lower—between £13 and £15 million as compared with between £15 and £17 million. Further experiments and investigations would be required before a final choice could be made.

From the flood protection aspect, the barrier scheme is decidedly preferable to the raising of the riparian defences, since the former would provide a standard of protection 6 ft. above 1953 levels whereas the latter could only reasonably be raised by about 3 ft.

The next stage is that consultations between interested parties will take place with the view of establishing the degree of support for the proposals and considering the arrangements for putting them into effect.

Flood Economics

It is often found with flood protection works, and the case of London is no exception, that the capital cost is high and the need only patently demonstrated at infrequent occasions. In these circumstances, there is an understandable tendency for the urgency accorded to a particular scheme to diminish progressively with the time which has elapsed since the last flood. A gamble with fate is tempting when the odds are long, but it is generally advisable to be cognizant of the stakes.

The worthwhileness of a protection scheme may be assessed on an economic basis. This entails a comparison between the cost of protecting against a particular flood, and the cost of the damage which would otherwise result. It is of course necessary to take into account the likely interval of recurrence of the flood, and this may be estimated by statistical methods.

The danger to public safety and the damage which would be associated with various degrees of overspill in London have not been generally made known. It is significant, however, that the Dutch are planning the Delta scheme on the basis of a flood with a 10,000-year recurrence interval. This standard may be compared with the estimated 400-year interval of the 1953 flood.

ARID ZONE PROBLEMS

A GENERAL symposium on the "Problems of the Arid Zones" was held at Unesco Headquarters in Paris during May 11–18. It was attended by more than two hundred delegates, representing twenty scientific disciplines, from thirty-four countries, the latter including all the major arid areas of the world; the U.S.S.R., the United States, France and the United Kingdom were all well represented.

The symposium was opened by Mr. Vittorino Veronese, director-general of Unesco, who warmly welcomed the distinguished delegates from so many countries. He directed attention to the importance of the arid zones, which cover one-third of the Earth's surface, in relation to the need for increasing the food resources of the rapidly increasing world population, which has already reached the 2,000 million mark, and is expected to double itself within the next fifty years. The universal character of the results of research in the arid lands and the importance of employing them to the common good make this research a suitable field for international action, particularly through Unesco, which is charged by its constitution to promote scientific research with the view of improving the living conditions of mankind.

The director-general introduced the president of the symposium, M. P. Piganiol, delegate-general for scientific research of the Government of France, whose responsibilities cover the organization of scientific research in that country; he addressed the delegates on the main problems to be faced by the symposium, the principal object of which was to evaluate the results already achieved and to make recommendations regarding the future course of arid zone research.

The general arrangements for the symposium, which followed the recommendations of the Unesco Advisory Committee for Arid Zone Research at its meeting in Madrid in September 1959, were carried out with great care and efficiency by the Arid Zone Unit of the Unesco staff. Review papers covering the principal scientific disciplines were requested from acknowledged leaders in their particular fields, and the discussions that followed added considerably to the value of the papers. The Proceedings of the symposium, which should be of considerable scientific interest and value, will be published in English and in French by Unesco in its Arid Zone Research Series.

In 1951 Unesco was given the task of promoting research in the arid zones, which for this purpose are taken as including also the semi-arid areas; by an extension of stock raising and the building of great new irrigation schemes in suitable areas, these zones are capable of augmenting considerably world food supplies. This basic research led to such interesting and useful results that in 1957 the activities were raised to the rank of a major project, whereby increased funds were made available for it with special reference to the arid belt extending across northern Africa from Morocco to Egypt and thence through the Middle East to Pakistan and India. Following eight years of activity on the many facets of arid zone research, including three years devoted to the major project, the general symposium has been held with the object of reviewing the results of this research and to suggest new directions of useful activity.

Also, since the major project is due to be terminated at the end of 1962, this review had to be made now in order to provide in good time for the continuation of arid zone research after 1962. The General Conference of Unesco in 1958, in approving the holding of the general symposium, had directed the director-general to submit to it in November, 1960, a report on the past effectiveness, and recommendations for the future course, of the major project, on the basis of the study and recommendations of the symposium.

In order to achieve this purpose, the symposium was divided into four parts.

(1) Critical Appraisal of the State and Perspectives of Knowledge in the Various Scientific Disciplines Involved

For this part of the symposium, review papers were presented in the following fields of science, most of which have formed the subjects of symposia or research reviews organized under the Unesco Arid Zone Programme:

(i) Surface hydrology (including sedimentation)—Dr. W. B. Langbein, U.S. Geological Survey, Washington.

(ii) Geology, geomorphology and ground-water hydrology—Dr. F. Dixey, former director of Overseas Geological Surveys, London.

(iii) Climatology (including hydro-meteorology)—Dr. C. C. Wallen, Swedish Hydrological and Meteorological Service, Stockholm.

(iv) Microclimatology (physical and biological)—Prof. W. R. Van Wyk and Prof. J. de Wilde, Agricultural University, Wageningen.

(v) Soil science (including soil conservation)—Dr. Georges Aubert, Chef du Service des Sols de l'Office de la Recherche Scientifique et Technique Outre-Mer, Paris.

(vi) Salinity problems of plants and soils—Dr. H. E. Hayward and Dr. L. Bernstein, U.S. Salinity Laboratory, Riverside, California.

(vii) Plant physiology—Prof. M. Evanari, Hebrew University, Jerusalem.

(viii) Plant ecology—Prof. G. Lemée, Faculté des Sciences, Paris, and Prof. L. Emberger, Institut de Botanique, Montpellier.

(ix) Human and animal physiology and ecology (including human and animal population problems)—Dr. D. H. K. Lee, Quartermaster Research and Engineering Command, Natick. Development of arid lands and its ecological effect on the insect fauna—Dr. B. P. Uvarov, former director, Anti-Locust Research Centre, London.

(x) Local energy sources—Mr. E. W. Golding, Electrical Research Association, London, and Dr. Tabor, National Physical Laboratory, Jerusalem.

(xi) Saline water conversion—Dr. E. D. Howe, College of Engineering, University of California, Berkeley.

(2) Appraisal of Unesco's Activities in Promoting Research and Training related to Arid Zones

This was supplemented by reports on related activities of international governmental organizations and by reports from Member States in the major project areas.

Under this heading was presented a comprehensive report by the Secretariat describing Unesco's activities under the major project and the preceding arid zone programme in organizing the symposia and research reviews already referred to, the financial and technical assistance given to a number of research institutes within the arid zone, as in Egypt, Israel, India and Pakistan, the organization of training courses in hydrology, plant ecology, microclimatology, etc., required by the scientific staff of arid lands, and the granting of fellowships in such subjects; the report also underlined the results achieved and the difficulties encountered. The United Nations Water Development Centre, the United Nations Special Agencies, including the Food and Agriculture Organization, the World Health Organization, and the World Meteorological Organization, the international scientific organizations, including the International Union of Geodesy and Geophysics, the International Geographical Union, and the International Commission on Irrigation and Drainage, and the Commission for Technical Co-operation in Africa South of the Sahara, also submitted reports of their activities and plans in relation to the arid zone. Finally, most of the Member States of the region of the major project submitted similar reports.

These various reports demonstrated the close collaboration that exists between Unesco and the Special Agencies, and certain international scientific bodies, in the joint attack on the problems of the arid zones; for example, Unesco co-operated with the Food and Agriculture Organization on a desert locust ecological survey, on an ecological map of the Mediterranean area, and on forest and grazing policies in arid and semi-arid areas, with the World Meteorological Organization on the measurement of solar radiation and on a climatological survey of solar radiation, with both Organizations on an agro-climatological study in arid and semi-arid areas of the Mediterranean region, with the International Association of Scientific Hydrology in certain hydrological and hydrogeological problems, and with the International Commission of Irrigation and Drainage on the prevention of evaporation losses from irrigation systems.

(3) Studies on Selected Problems Illustrating Difficulties in Translating Knowledge into Action in Arid Zone Research, Training and Development

Since it had become increasingly clear with widening experience that a considerable gap tends to develop between the accumulating scientific knowledge of the problems of the arid zone and its application in daily life by the pastoral, agricultural and other inhabitants of the lands concerned, papers were called for devoted essentially to the difficulties of translating knowledge into action in certain typical situations; accordingly papers were presented under three main headings as follows:

(i) *Nomadism in relation to grazing resources.* The Sahara and the Sahel—Prof. R. E. Capot-Rey.

Moving of flocks in the Sahelian zone—O. Bremand and J. Pagot (Prohuza).

The Near East Arab countries—Dr. Mohammed Awad, Cairo.

The mountain and plateau areas of South-West Asia—Dr. F. Barth, Norway.

Nomadic pastoralism—Food and Agriculture Organization, Rome.

(ii) *Alternative uses of limited water supplies.* Studies were presented underlining approaches in four distinctive regions as follows:

United States. Water and the arid zone—Dr. L. Leopold, U.S. Geological Survey, Washington.

Algeria. Possibility of using minor water resources—Mr. G. Drouhin, Director de l'Hydraulique et de l'Equipement Rural, Algiers.

United Arabic Republic. Egyptian region—Dr. Youssef Simaika, technical adviser, Ministry of Public Works, Cairo.

U.S.S.R. Basic trends and methods of water control—Prof. A. N. Askoschensky, member of Lenin's Academy of Agricultural Sciences, Moscow. Also, Prof. Gilbert White, University of Chicago, considered these regional aspects in a review paper on alternative uses of limited water supplies.

(iii) *Public awareness and the educational problem.* Under this heading were submitted papers related to certain special problems in arid zones as follows:

Agriculture (Israel)—Prof. D. Weintraub, Hebrew University, Israel.

Irrigation and land use (Pakistan)—Dr. A. G. Ashgar, Pakistan.

Mineral resources (Sahara)—J. Petit, Prohuza, French Research and Information Centre on Human Problems in Arid Zones.

Agriculture: extension work in the Near East—Z. Behravesh, Food and Agriculture Organization.

(4) Study of the Perspectives for Future International and National Action in Arid Zone Research, Training and Development

The discussion at this concluding session of the symposium was based on the previous papers and discussions, and on a paper prepared by Unesco showing the administrative, financial and other considerations to be taken into account in submitting proposals for an extension of Unesco's arid zone research programme.

From this discussion it was clear that the symposium was unanimously of the opinion that the Unesco arid zone research programme should be continued for some years at not less than the present level, and that it should be extended particularly to cover the Latin-American countries; it was considered also that the organization of training courses and fellowships should be expanded. In addition, it was recommended that the Advisory Committee should continue to function on its present lines. Finally, many new projects and lines of research were suggested, including particularly an international study of the artesian basins of northern Africa; the extension of integrated surveys, including surveys relating to geology, geomorphology, water supplies, pedology, plant ecology and microclimate; the study of plant response to environmental factors; soil biology; insect pests and plant diseases; diseases linked with irrigation systems; and human environmental physiology.

The suggestions and comments made at the symposium were examined by the Unesco Advisory Committee on Arid Zone Research in a special review session held immediately afterwards, and they will be taken carefully into account when the Unesco governing bodies come to consider the future of arid zone research. The Advisory Committee met also during the two days prior to the symposium, and the Sub-Committees on Cartographic Problems in the Arid Zones, and on the Socio-Economic Problems of the Arid Zones, also held meetings at this time.

During the symposium there was an exhibition of maps, photographs and publications illustrating the activities of Unesco, the member States and other bodies; two excellent films were also shown—the Unesco film, "Arid Lands", produced by World Wide Pictures, Ltd., based mainly on scenes and research activities in Pakistan, Israel and Morocco, and a Russian film depicting arid zone development, in respect of irrigation, dry farming and stock raising, in the Karakum and other deserts of the U.S.S.R. Also, a party of delegates visited the phytotron being set up at Gif-sur-Yvette by the Centre National de la Recherche Scientifique; the studies in plant physiology at the phytotron, with special reference to growth under varying conditions of light and temperature, were demonstrated by the director, Prof. P. Chouard.

In respect of the high standard of the papers presented, of the many countries of the arid zone represented, and of the free discussions that followed the papers, the symposium marked an important stage in the study of the arid zones; moreover, it afforded a valuable review of present knowledge and of the scope and nature of future research, and it clearly achieved its objective in presenting, for the consideration of the governing bodies of Unesco, a unanimous and broadly based opinion on the importance of maintaining arid zone research and training at a high level.

Whatever may be the final decision, Unesco's achievements to date will rank high as a contribution to science in making known the problems of the arid zones, and in assisting in their scientific investigation, thereby leading also to the increased economic and social development of these lands. F. Dixey

SELF-REGULATION IN LIVING SYSTEMS

THE Ottawa symposia on "Self-regulation in Living Systems" organized by Dr. D. K. C. MacDonald of the National Research Council shows signs of becoming an annual series (*Nature*, 184, 239; 1959, and 183, 370; 1959). The third meeting was held on March 4, in Montreal, with the Montreal Neurological Institute and McGill University as joint hosts. The attendance exceeded thirty people, representing most medical branches, physics and engineering. The theme was "Tremor", and on this occasion the topics of discussion were introduced by clinicians and illustrated with the willing co-operation of patients. Discussion during the day was general and spirited.

Dr. F. L. MacNaughton (Montreal Neurological Institute) introduced the subject of 'clonus' (alternating contractions and relaxations of muscle). A patient with ankle clonus was introduced and subsequent discussion on the mechanism of oscillation was therefore restricted to this example. The oscillation could be initiated by a sharp application of force to the ball of the foot, and was sustained as long as the force remained. Simultaneous but asynchronous oscillation of both feet could be produced. The oscillation frequency was about 4 c.p.s. and increased only slightly with pressure. The disease had been caused by a spinal tumour pressing on the spinal cord; the tumour had recently been removed and there was some slight improvement in the patient's condition. She was paralysed from the waist down and could not feel the clonus directly. MacNaughton explained that the disease was known to be caused at the spinal cord level, rather than higher in the central nervous system. Ankle clonus was produced mechanically by involuntary contractions of the leg's rear lower muscle (gastrocnemius) followed by relaxation under action of the external force. Clonus was not produced by a coupled oscillation between the rear and front leg muscles, and disappeared if the afferent stretch receptors in the gastrocnemius were cut. Any healthy person can produce clonus, for example, by trying to lift an unliftable weight.

After this discussion Dr. MacDonald (National Research Council) exhibited a simple closed-loop system as an illustration of the instability features discussed above. In this demonstration a galvanometer mirror deflected a light beam so as to follow the physical movement of a photo-cell. Normal stable following was produced by negative feedback at some gain. Sufficiently increased gain, however, drove the light spot into a tremor, as did increase of the controllable time-delay in the circuit.

Dr. Burns (McGill) discussed the physiology of the basic causal loop; that is, muscle-stretch receptor—multiple afferent nerves—spinal cord—multiple motor neurons-muscle. With nerve propagation speed of order 10^2 m./sec. and nerve-length of order 1 m., the propagation time of the nerve in the loop is 20 msec. (2 nerves); other lag-times in the circuit are negligible. This loop delay-time would produce an oscillation of 25 c.p.s. if it were the direct cause of clonus, but this provides poor correlation with the observed 4–10 c.p.s., and of course this closed-loop action is the same in normal healthy voluntary actions.

The situation is complicated by the fact that the components of a multiple-nerve system do not fire simultaneously, but rather in a statistical pattern approaching a Gaussian distribution of frequency, and propagation velocities are also distributed about a mean in the range 70–120 m./sec. Furthermore, the excitability of a nerve follows a time pattern after firing as indicated in Fig. 1.

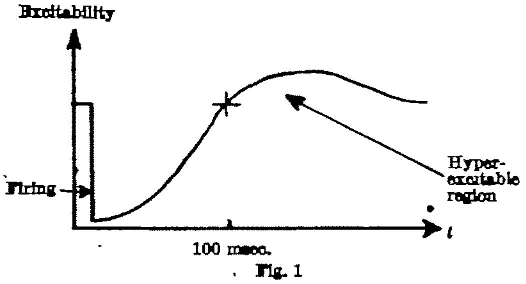

Fig. 1

In discussion, Dr. Burns wondered whether the nerves in clonus might fire almost simultaneously due to hyperexcitability. The observed oscillation frequency corresponds well to a closed-loop oscillation based on the 100-msec. time-delay to hyperexcitability in a nerve after firing.

In the afternoon, Dr. MacNaughton introduced a patient with Parkinson's disease. The particular symptom studied was a tremor of the thumb and forefinger, in the frequency range 3–5 c.p.s. Amplitude increased with concentration, excitement and fatigue, but disappeared during sleep. Application of a heavy weight to the hand only reduced the amplitude. Purposeful action of the hand was quite possible and tremor decreased during a 'slewing' action, but increased, for example, as the hand approached the pen it was going to pick up.

Dr. Blundell (Montreal Neurological Institute) discussed the tremor problem from the point of view of the surgeon, particularly in relation to Parkinson's disease. Surgical possibilities are: (1) To cut the motor nerves; but then no movement is possible. (2) To cut the afferent nerves. This removal of feedback would be justified in extreme cases if it overcame incapacitating tremor. This is true of clonus, but in one known operation on a Parkinsonian case, tremor remained, although at a different amplitude. (3) To cut in the area of the central nervous system. This is the current field of research. Results so far are rather conflicting, and there is insufficient knowledge for confident surgery. Dr. Blundell then detailed the following possibilities as tremor producers: (1) servo-loop oscillations; (2) rhythmic oscillations, for example, by a steady driving mechanism in the brain; (3) hyperexcitability of cells, due to disease.

Dr. Burns also developed the physiology of muscle action somewhat further. Recently a second loop (the 'gamma' loop) has been identified by which 'small' motor neurons are fired from the spinal cord to contract the fibre which is measured by the length receptor. In addition, the afferent nerves from the stretch receptors communicate with the central nervous system. In turn the central nervous system communicates with both the 'big' and 'small' motor neurons. Several more loops are thus added, and much remains to be learned of the combined control action.

Dr. Jasper (University of Montreal) described extensive experimental measurements on tremor, being carried out at the University of Montreal, using micro-electrodes. Frequency measurements of the action potential of muscles in clonus and Parkinson's disease look exactly alike. On the other hand, the cortical phenomena seem different. Some 15–20 per cent of the cortex cells seem to show activity correlated with tremor, but not enough is yet known. In monkeys, tremor has been produced by a small cut in the brain in the appropriate area; a 'large' cut can then remove the tremor.

Finally, Dr. J. A. Tanner (National Research Council) reported the work being done by Massachusetts Institute of Technology and Yale University on measuring the impedance of the wrist and finger extremities when subjected to sinusoidal or stochastic vibrations. The impedance falls with frequency as might be expected for an inertial load, except that in healthy people there are resonant peaks in the 7 and 17 c.p.s. regions. These are as yet unexplained. In patients with tremor the major resonance is due to the tremor, but at a different frequency than the tremor itself, lying between the 7–17 c.p.s. peaks. This overshadows the other resonances, naturally enough.

A spirited discussion followed concerning the relative usefulness of the 'black box' technique as illustrated by the impedance measurements just described, and the classic analysis-techniques in which individual elements are isolated and their characteristics learned before they are combined together. Everyone agreed that the latter method is ideal if it can be used. Opinion was divided as to whether the 'black box' techniques could be useful, since the 'black box' may often be altogether too complex. I myself feel that both approaches are useful and must be pursued in parallel. This in fact is done of necessity in both engineering and medicine at least.

J. H. MILSUM

SCHIZOPHRENIA AND LOW-GRADE MENTAL DEFICIENCY IN SWEDEN

A CLINICAL and genetico-statistical analysis of schizophrenia and low-grade mental deficiency of a large rural population of 25,000 people in Sweden indicated that altogether 1,790 individuals belonging to 231 families were suffering from schizophrenia, and 1,541 individuals belonging to 215 families were low-grade mental defectives*.

Of the cases of schizophrenia, 50 per cent were classified as hebephrenic, 33 per cent as catatonic, 10 per cent as paranoic and 7 per cent as atypical. 70 per cent of the cases had symptoms generally described as catatonic, but only 20 per cent had them in connexion with the onset of the psychosis.

The mean age at onset of schizophrenia among females, 32 years, is significantly higher than that, 28 years, among males. The psychosis had an acute onset in approximately 40 per cent of the cases and a periodical course in many cases, there being no sex difference. There is thus a positive relationship between acute onset of schizophrenia and periodical course of the psychosis.

There was a statistically significant association between schizophrenia and mental deficiency. Such an association has not been statistically established previously. The morbidity-rate for mental deficiency—including high-grade defectives—among the schizophrenic propositi is 10·5 ± 1·9 per cent as against a risk of 3 per cent estimated for the general population. The morbidity-rate for mental deficiency among the sibs of propositi was no higher than the risk in the general population of the area studied, nor was the rate of schizophrenia among the sibs of propositi affected with low-grade mental deficiency increased.

---

* A Clinical and Genetico-Statistical Study of Schizophrenia and Low-Grade Mental Deficiency in a Large Swedish Rural Population. By Bertil Hallgren and Torsten Sjogren. (*Acta Psychiatrica et Neurologica Scandinavica*, Supplementum 140, Volumen 35, 1959.) Pp. 65. (Copenhagen: Ejnar Munksgaard, 1959.)

The genetico-statistical analysis confirms the conclusions of previous investigations that specific genetic factors are of importance for the manifestation of schizophrenia. The morbidity-rate for schizophrenia as well as that for non-psychotic mental abnormalities among the sibs of propositi was significantly higher in the families where one of the parents was affected with psychosis or non-psychotic mental abnormality (mainly severe personality deviations) than in those where both parents were unaffected.

Of the mental defectives 88 per cent belonged to the group of uncomplicated, undifferentiated mental deficiency. In 4·1 per cent of the cases the mental defect was combined with epilepsy, in 3·3 per cent with deaf-mutism and in 2·6 per cent with spastic paresis. These figures are considerably higher than corresponding frequencies of epilepsy, deaf mutism and spastic paresis in the general population.

The genetico-statistical analysis confirms the findings of previous investigations that specific genetic factors are of importance for the manifestation of undifferentiated low-grade mental deficiency. In the unclassified material, the morbidity-rate for the low-grade mental deficiency among the sibs of propositi with uncomplicated undifferentiated mental deficiency is 8·4 ± 0·9 per cent. This rate is significantly higher than the corresponding risk, 0·9 per cent in the general population. The rate among brothers, 11·3 ± 1·5 per cent, is significantly higher than that among sisters, 5·6 ± 1·1 per cent.

RADIOACTIVE FALL-OUT IN GHANA

By Dr. A. H. WARD and J. D. MARR*

Physics Department, University College, Legon, Ghana

ROUTINE radioactive survey measurements were started in Ghana in October 1959, after the announcement of French atomic testing plans at Reggan in the northern Sahara. The measurements were extended in January 1960, and the first atomic explosion at Reggan was on February 13. It gave a peculiarly simple variation of radioactive fall-out in Ghana, as it was a single isolated test, after all other fall-out levels had fallen considerably following the cessation of atom bomb tests in 1958. The unexpected relatively large increase in radioactivity of samples of dust, crops, soil and water is summarized; most of the measurements were by gross β- or γ-counting, and no chemical separation has yet been made.

Radioactivity-levels were very low in Ghana before February 13; there is little natural uranium or thorium in the country, and because of Ghana's position near the equator, world-wide fall-out from earlier atomic tests had produced only very slight contamination. Daily measurements since January of activity in air-borne dust, deposited dust, and milk have been made at two laboratories, and the main results are shown in the two graphs. Tamale is in the Northern Region of Ghana, 1,000 miles south of Reggan, and the Accra laboratory is at Legon, 8 miles from the coast and 1,400 miles south of Reggan.

The graphs show the daily measurements of radioactivity in air-borne dust per cu. m., and in deposited dust per sq. m. per day. Air-borne dust is collected by filtration under forced flow, using the method developed by the Radiation Protection Division of the Canadian Department of Health and Welfare; an air pump is fitted with a glass-fibre filter paper and with the average loading of dust has a capacity of about 720 m.^{3} a day. Each pump and filter is in a Stevenson screen, that at Tamale being 3 ft. above ground-level, that at Accra being on a flat roof 21 ft. above ground-level. Deposited dust was swept up daily from a measured area of flat concrete roof, 21 ft. above ground-level at both Tamale and Accra; during peak periods the same area was swept each day until any remaining activity was negligible.

The contamination reaching Ghana was dust-borne, and from the graphs the bulk of the contamination appears to arrive between the third and tenth days after the explosion. Thereafter, the daily arrival of contamination is seen to fall off slowly; some of the delayed arrival may be 'secondary' in origin, as dust was blowing up freely from all soil and sand surfaces in Ghana and in the Sahara at this time, due to the extremely dry weather conditions. The fall-off in daily arrival of contamination is, however, more rapid than the radioactive decay of mixed fission products, indicating that the total radioactivity carried by this 'secondary' dust is very much less than in the original bulk of contaminated dust direct from Reggan.

The decay of each sample is complicated. All air filters collect natural radium and thorium daughter products as well as fall-out radioactivity. The radium and thorium daughter products decay rapidly, and their effective $\mu\mu$c./m.^{3} content is shown on the graph up to February 16. After this date, the fall-out alone is shown; from repeated counts the contribution of the longer-lived fall-out can be separated from the rapid decay of the radium and thorium daughter products. On the other hand, for deposited dust the total radioactivity content is shown in all cases. Each sample of fall-out has been stored and counted repeatedly to establish its own decay scheme. Apart from some of the 'peak' samples which initially decayed more rapidly, all samples gave a rate of decay fitting closely to the curve:

$$I_t = I_4 t^{-1.2} \text{ (from } t = 4 \text{ days onwards)}$$

Dust particles varied in size, and it seemed likely that the larger particles were more local in origin than the smaller ones. Specimens of collected dust were therefore passed through a 50-μ sieve, and it was found that the specific activity of the transmitted

---

* Technical adviser loaned to Ghana by Canadian Government.

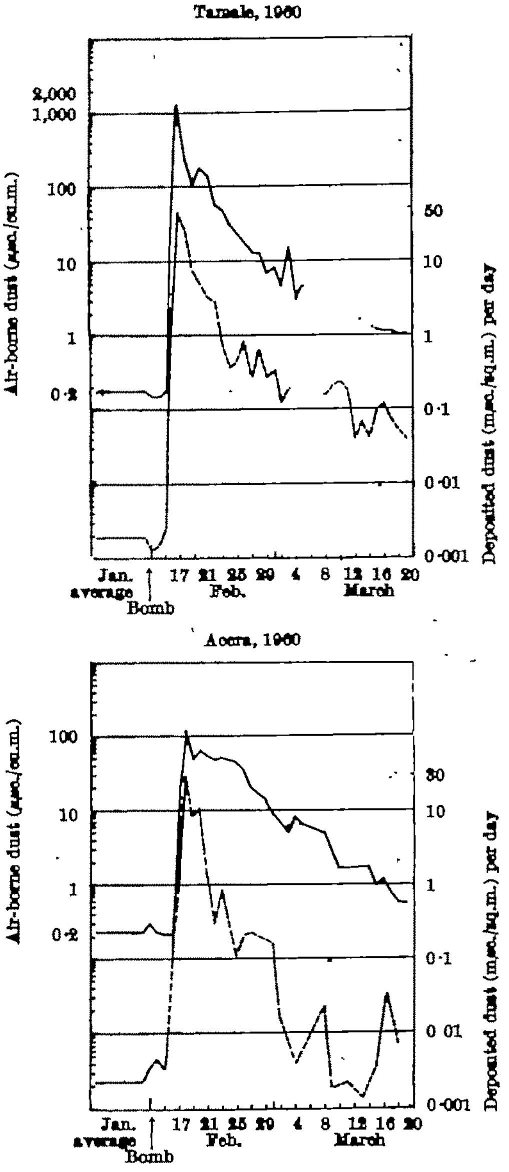

Fig. 1. Air-borne dust (full line) and deposited dust per day (dashed line) showing the January average, and the rise after the bomb test of February 13

particles was forty times greater than that of the retained particles.

Rain fell at the Legon laboratories, Accra, on March 2 and 6, with an average activity of 60 mμc./l. The average pre-bomb activity was 0·013 mμc./l. Little rain fell at Tamale until mid-March; but milk from two local grazing herds of cows showed a small increase on February 18, from a pre-bomb average of 1·8 counts/min. per 10 ml., to counts of 3·7, 2·8, 2·6, 3·6 and 4·0 for the days February 18–22.

From the other thirty stations in Ghana, samples of dust deposited over weekly periods, of exposed leaves and top soil, were sent to the main laboratory at Legon for β and γ analysis. In addition, transistorized equipment was taken by 'Landrover' on a survey of northern Ghana. The results give a simple area and time variation which is consistent with the detailed analyses from the Tamale and Legon laboratories.

The γ counting of top soil probably gives the best measure of cumulative fall-out, but β- and γ-counting of exposed leaves and of dust swept from measured areas of flat concrete surface provides useful confirmatory figures. The average of all measurements for the cumulative fall-out up to the three dates shown is given below, in units of $m\mu c./m.^2$. The high, medium and low counts correlate well with the 'north' (nine stations), 'central' (thirteen stations) and 'south' (eight stations) of Ghana (Table 1).

Table 1

	Pre-bomb average	Cumulative to Feb. 20	Cumulative to Feb. 27	Cumulative to March 18
North	11	126	55	13
Central	13	42	16	5
South	12	17	6	3

The first column refers to soil samples only, for a 2-in. deep section of top soil; these pre-bomb figures, or equivalent 'deep soil' samples after the test, have been subtracted from top soil counts to give the cumulative fall-out figures of the last three columns. Pre-bomb leaf measurements gave negligible counts even with a Philips-type low-background counter; pre-bomb dust figures are very small, and have been subtracted in the graphs and table above. The separate station figures on which the averages in Table 1 are based vary considerably; the highest level found in Ghana was 4·6 times the average 'north' figure.

On leaf samples of February 20, most of the radioactivity could be washed off, and so was attributed to surface dust; in later leaf samples more of the contamination was 'fixed' in the leaves.

The amount of dust radioactivity makes γ-spectroscopy very easy, even with a single-channel pulse analyser. γ-spectra taken from specimens of different ages after February 13 were found to be typical of mixed fission products of those ages, and these results were confirmed and extended by courtesy of two health physics laboratories in the United Kingdom.

The increased radioactivity-levels described above are much higher than those generally predicted for Ghana before the February 13 test at Reggan. Those familiar with local conditions had, however, anticipated that direct fall-out was a possibility, on account of the wind circulation which occurs for the period December–March, and its occasional unusual variations. Detailed wind trajectories from data taken during February 13–18 agree well with the observed times of arrival of the main increases of radioactivity, both in Ghana and Nigeria. The röntgen doses from these increases, however, are still low. Calculations from the $m\mu c./m.^2$ figures, together with a few direct dose-rate readings, assuming a $t^{-1\cdot 2}$ decay, indicate a total gonad dose for the maximum 'north' fall-out of less than 1 millirad for the year from the first French bomb test. It is considered by many authorities that an additional dose to a whole population of 500 millirads is acceptable genetically.

We wish to thank the Ministry of Defence of Ghana for financing the work and for permission to publish these results, and to acknowledge the valuable assistance of the professor of physics, members of his Department, and the Director of Meteorological Services in Ghana.

RADIOACTIVE LABELLING OF LEPIDOPTEROUS LARVÆ: A METHOD OF ESTIMATING LATE LARVAL AND PUPAL MORTALITY IN THE WILD

By L. M. COOK
Department of Zoology, University of Oxford

AND

DR. H. B. D. KETTLEWELL
Genetic Laboratories, Department of Zoology, University of Oxford

THE special advantages of marking insects by means of radioactive tracers have been explained in a previous communication by one of us[1]. It was pointed out that the technique allows even holometabolous species to be detected through successive instars and between stages in metamorphosis. A method was described for calculating pupal mortality using individuals marked as larvæ. Phosphorus-32 was employed for species with a rapid metamorphosis (*Locusta migratoria* L. and *L. pardalina* Walk.), and sulphur-35 for those with a longer life-history (*Panaxia dominula* L.)[2]. This work was conducted under laboratory conditions, and no field releases were undertaken at the time. The marking of adults by feeding a radioactive tracer to the larvæ has been carried out on a number of occasions[3-5], but the unique advantages of this method of recording individuals in studies of population dynamics have not so far been fully utilized. We present here the results of two estimations of late larval and pupal mortality under natural conditions in colonies of the moth *Panaxia dominula* (L.).

I. 1953 (H. B. D. Kettlewell)

The colony of *P. dominula* at Sheepstead Hurst, Berkshire, was studied for some years by Dr. P. M. Sheppard[6]. He estimated the total size of the adult population in each season using Fisher's multiple recapture method[7]. In 1953 a sample of larvæ was taken from this colony and fed on deadnettle (*Lamium* spp.) which had been grown in water culture containing sulphur-35. 1,227 larvæ were returned to the colony, each giving 20 counts per minute or more above the background when scanned under a Geiger counter. Larvæ with counts as low as this can be used because the earlier work had shown that the recorded activity in the imagines is always two to six times greater than that in the same individual when scored as a larva more than two months earlier. Sulphur is present in the wings of the adults, but in the larvæ it is principally internal, and the low larval count is due to the low penetrating power of the isotope.

The larvæ were extremely abundant in 1953, and in view of the heavy predation by cuckoos (they are probably the main visual predators of the species), it was decided to shoot one some days after the release. The remains of about 25 *P. dominula* larvæ were present in the gizzard, but none gave radioactive counts, nor did the intestine, liver, heart or any other part of the cuckoo. I did, however, note that there was a complete absence of larval hairs and skins in the small intestine, which suggests that the cuckoos regurgitate the larval roughage, probably in the form of small pellets.

In July 1953 the total adult population in the colony was estimated by Sheppard[6] to be between 20,000 and 26,000. In the course of the sampling from which this estimate was obtained, each captured insect was taken to the laboratory and scanned before being released again into the colony. The labelled insects were clearly distinguishable from non-radioactive ones, the lowest count recorded being 76 c.p.m. above background. The results are given in Table 1.

Table 1. NUMBERS OF RADIOACTIVE INDIVIDUALS IN RANDOM SAMPLES OF IMAGINES

Date	Number of radioactive insects	Total sample
1.7.53	—	80
2.7.53	—	99
3.7.53	—	125
4.7.53	—	207
5.7.53	—	127
6.7.53	2	119
7.7.53	4	229
8.7.53	5	160
9.7.53	3	285
11.7.53	0	164
12.7.53	0	251
13.7.53	1	259
14.7.53	0	276
15.7.53	2	141
16.7.53	0	316
17.7.53	0	211
18.7.53	0	180
19.7.53	1	210
21.7.53	0	197
22.7.53	0	143
23.7.53	0	148
24.7.53	0	111
	18	3,400 + 638 = 4,038

$$\text{Total larval population} = \frac{\text{radioactive larvæ released} \times \text{total imagines caught}}{\text{radioactive imagines caught}}$$

The imagines were not scanned on the first five days of collection; but using the ratio of the number of labelled insects to the total number in the sample from which they are recorded as an estimate of the frequency of radioactive individuals in the population, the mean number of larvæ is calculated to be 231,767. The data suggest that marked individuals emerged slightly in advance of the rest of the population, however, so they may have been present at a higher frequency in the first few days. This is possibly because they were kept at a slightly higher temperature than the rest of the population during the 48-hr. feeding period. Inspection of the scatter of their distribution in the later samples suggests that 5 or 6 may have been present, and to recalculate the larval population size the figures 4 and 7 have been used. Assuming the number of marked insects in the total sample of 4,038 to lie between 25 and 22, the mean number of larvæ is estimated to be between 198,185 and 225,210. With a total adult population of approximately 23,000 this gives an estimate of mortality over the intervening period of 88–90 per cent.

It was apparent that the marked larvæ could be recognized clearly when recaptured as adults; and no difference was observed between the viability of radioactive and non-radioactive controls. It was therefore decided to employ the same technique again to assess late pre-adult mortality, this time in a very small colony which had thrived for some years in a wild state in the vicinity of Oxford, following its original introduction from a laboratory stock.

2. 1959 (L. M. Cook)

The larvæ were marked in the same way as before. When nearly full grown they were fed on radioactive *Lamium* for 24 hr., care being taken to ensure that the temperature was as near that prevailing in the colony as possible. 165 larvæ were returned to the population immediately after feeding. At the same time four containers were set up with mixed batches of radioactive and non-radioactive larvæ as controls. The moths from them were scored as they emerged, and despite the fact that there was heavy over-all mortality during pupation there is no evidence that it is distributed differentially between active and non-active larvæ (Table 2). The marked moths showed no tendency to emerge earlier than those which were not radioactive.

Table 2. SURVIVAL OF CONTROLS

	Radioactive	Non-radioactive
Total number of larvæ used	30	30
Number of adults which emerged	4 4 3 4	7 3 8 1
Total adult emergence	15	19

$\chi^2_{(1)} = 0·27, P > 0·5$

Because of the small size of the colony environmental conditions in it were relatively uniform and emergence of adults took place over a very short period of time. A close watch was kept from the beginning of June onwards, and sampling was carried out every day throughout the season. As the moths in the colony emerged they were captured, scanned, marked with a spot of cellulose paint (receiving a distinct mark each time they were caught), and then released. The larval population size has been calculated from the single capture-recapture equation using Bailey's correction[8] and the adult population size by Fisher's method[7]. A summary of the data is given in Table 3. The mean number of larvæ present when the labelled sample was released is estimated as 1,210, and the mean number of adults as 77. The mean value for the mortality over the period between the two estimates is 94 per cent.

The estimation in two different colonies at different times suggests figures for late larval and pupal mortality which are between 85 and 95 per cent. The adults lay about 200 eggs, or approximately 100 per individual. The population at Sheepstead Hurst comprised 6,000–8,000 individuals in 1952 (ref. 9), so that the number of larvæ which remained of the 1952–53 generation at the time when they were sampled was only about one-quarter of the total number of eggs produced. Thus, there is heavy mortality in the late stages of development after an appreciable drop in numbers has already taken place. The implications of this situation will be discussed elsewhere. The work presented here demonstrates for the first time that estimates can be made in wild populations, using a radioactive labelling technique, which are of sufficient accuracy to stand as the basis for such a discussion. The method is capable of very wide application to studies of natural populations of insects.

Table 3. POPULATION DATA FOR 1959

Days from first release	June 21	22	23	24	25	26	27	28	29	30	July 1	2	3

ZINC CONTENT OF ERYTHROCYTES AND LEUCOCYTES OF BLOOD OF NORMAL AND LEUKÆMIC SUBJECTS

By E. DENNES, R. TUPPER and PROF. A. WORMALL, F.R.S.

Department of Biochemistry, Medical College of St. Bartholomew's Hospital, London, E.C.1

MANY studies have been made on the significance of zinc in the eye, pancreas, the male genital tract, and other tissues of the animal body[1,2]. Since the recognition that carbonic anhydrase is a zinc enzyme, with the metal as an integral part of the enzyme molecule[3,4], considerable progress has been made, largely by Vallee and his colleagues[5], in characterizing the alcohol dehydrogenase, glutamic acid dehydrogenase, lactic dehydrogenase, and carboxypeptidase, as zinc metalloenzymes. Also, zinc ions increase the activity of many enzymes, and there appears to be little doubt that this metal has important biological functions relating to cellular oxidation and possibly other aspects of metabolism.

Zinc is present in blood plasma, in which the metal is largely bound to the β-globulins (ref. 6 and unpublished work by us), and in erythrocytes and leucocytes, and although the last-named cells contain only about 3 per cent of the whole-blood zinc[7], the individual leucocyte is relatively rich in this metal, and "probably contains more zinc than does any other cell in the body"[8]. A protein which contains 0·3 per cent of zinc and which accounts for about 80 per cent of the leucocytic zinc has been isolated from normal human leucocytes[8,9], but as yet there is no information about the function of this protein. In work on the zinc content of the blood of five individuals suffering from myeloid leukæmia and three from lymphatic leukæmia, Vallee and his colleagues found that the zinc contents of the leukæmic leucocytes (expressed as µgm. zinc/10^8 cells) were exceptionally low, ranging from 10 to 40 per cent of the normal values, and they suggested[10] that "one characteristic of the blood dyscrasias known as leukæmia is an inability of the leucocytes to attain a normal zinc content". Wolff[11] has also obtained relatively low values for the serum zinc and the leucocyte zinc of leukæmic patients.

During recent years we have studied the uptake of zinc by normal and tumour tissues of mice, and we have measured the zinc content of the blood cells of normal subjects and individuals suffering from various types of leukæmia. The determination of the zinc in human leucocytes presents many problems. It is necessary to prepare leucocyte suspensions which are practically free from erythrocytes, and erythrocytes free from leucocytes, and an ultra-micro method of assay for zinc is required. For the separation of leucocytes, we have found dextran the most satisfactory substance to add to the blood to increase the rate of sedimentation of erythrocytes, as advocated by Wildy and Ridley[12]. We have estimated the amount of nitrogen in small samples of leucocytes or erythrocytes by Russell's colorimetric phenol–hypochlorite method[13]. For the zinc determinations, we developed a method of neutron activation analysis[14] which allows duplicate zinc determinations to be made on two or three drops of blood, or the leucocytes separated from 4 or 5 ml. or the red cells from about 0·2 ml. of human blood. The leucocyte samples used for each zinc determination contained 10^7–10^8 leucocytes and about 0·2–0·6 µgm. zinc.

We have made determinations on blood samples from 27 normal subjects and 22 leukæmic patients (15 subjects with chronic lymphatic leukæmia and 7 with chronic myeloid leukæmia), and we have found that the leukæmic leucocytes contained much less zinc (a mean value of 7·7 µgm. (*S.E.*, ± 1·3) of zinc, per 10^9 leucocytes) than did the normal leucocytes, the latter showing a mean zinc content of 14·2 ± 2·1 µgm. per 10^9 leucocytes. This difference between the leukæmic and normal leucocytes is statistically highly significant ($P = 0·02$).

Since leucocytes show considerable variation in size, measurement of the average zinc content per cell may not give the most satisfactory values for comparing the zinc contents of normal and pathological bloods, and we decided to calculate, in addition, the amount of zinc in the red and white cells in terms of µgm. zinc per mgm. of total nitrogen, in order to have a measure of the zinc/protein ratio. With these ratios also, the leukæmic leucocytes showed a very much lower zinc content than did normal leucocytes. The mean values (as µgm. zinc/mgm. total nitrogen) being 0·91 (± 0·08) and 1·97 (± 0·37) for the leukæmic and normal leucocytes respectively. Statistical analysis showed that this difference is highly significant (*P* between 0·01 and 0·02).

The amount of zinc in the erythrocytes shows a difference in the opposite direction, with the leukæmic erythrocytes giving a mean value of 1·13 (± 0·06) µgm. of zinc per 10^9 cells as compared with 0·96 (± 0·03) for the normal erythrocytes. The corresponding values for the erythrocyte zinc calculated as µgm. zinc per mgm. nitrogen were 0·26 ± 0·01 and 0·21 ± 0·01 for the leukæmic and normal bloods respectively. Statistically, this difference is highly significant (*P* between 0·02 and 0·05 for the zinc contents measured on a cellular basis, and between 0·001 and 0·01 for the ratios calculated on a nitrogen basis).

The whole-blood samples showed no significant difference between the values for normal and leukæmic subjects, and the relatively low zinc contents of the leucocytes, and the higher zinc content of the erythrocytes, in leukæmic blood as compared with normal human blood, did not appear to be related in any way to abnormally low or high levels of total blood zinc.

The relatively low zinc content of leukæmic leucocytes is of special interest to us at present, and we are making further investigations of this phenomenon. It is possible that the difference is due simply to the relative immaturity of the leukæmic leucocytes, and we are at present studying the zinc content of leucocytes associated with other types of leucocytosis. On the other hand, there is the possibility, as has been postulated by others, that the synthetic processes concerned with the formation of a zinc-protein or some other zinc compound associated with leucocytes, may be deficient in the leukæmic subject. In this connexion, it may be significant that our total nitrogen determinations have shown no significant difference between the amount of nitrogen (and presumably the amount of protein) present in the leukæmic leucocytes and that in normal leucocytes. A full account of these investigations will be published elsewhere.

This work was carried out with the aid of grants from the British Empire Cancer Campaign, and we are also indebted to Dr. T. E. Banks, of the Physics Department of this College, for continued valuable help with the maintenance of our equipment used for radioactivity measurements.

SERUM ALBUMIN CONCENTRATION IN ANALBUMINÆMIA AND ITS IMMUNOLOGICAL SIGNIFICANCE

By Dr. J. H. HUMPHREY
National Institute for Medical Research, London, N.W.7

BENNHOLD, Peters and Roth[1] recently described a brother and sister whose sera contained no albumin detectable by electrophoresis. If these persons completely lack human serum albumin, and their last contact with it resulted from transplacental transfer from their mother some 30–35 years ago, it might have been expected that they would treat human serum albumin as a foreign protein and react to transfusion by developing antibodies. In fact, extensive investigations[2] have shown that one of the subjects, who received repeated transfusions of human serum albumin, not only showed no signs of the increased elimination-rate which would have been expected had she formed antibodies, but actually catabolized transfused human serum albumin at about half the rate of normal persons. This raises the question whether albumin might have been present in the plasma in trace amounts even before transfusion, or whether the failure to develop antibodies was due to long persistence of immunological tolerance. The presence of traces of human serum albumin was therefore investigated by other techniques.

Through the kindness of Dr. Kallee a sample of serum was obtained, which was taken from the brother (Karl Br.) before any transfusions had been given. Using a rabbit antiserum specific for human serum albumin, and employing the quantitative precipitin technique, the serum was found to contain a substance reacting immunologically as human serum albumin in concentration 1·6 mgm./100 ml. The identity of this material with human serum albumin was confirmed by the agar-gel diffusion technique, in which the subject's undiluted serum gave a line continuous with that produced by albumin in normal human serum, and equivalent in concentration to that given by normal serum diluted 1/2000 (Fig. 1). Removal of antibodies to human serum albumin from the serum by adding a small excess of crystallized human serum albumin (Behring) prevented the formation of the line. Further confirmation was obtained by fractionation of the subject's serum with 22 per cent w/v sodium sulphate. The supernatant, after concentration by pressure dialysis to 1/3 the original volume, was subjected to paper electrophoresis. Most of the protein was α- and β-globulin, but there was a very faint trace of material with the electrophoretic mobility of human serum albumin.

Fig. 1. Agar-gel diffusion patterns with rabbit antiserum, before and after removing specific anti-human serum albumin by addition of a small excess of authentic human serum albumin
1, normal human serum 1/1,000 ; 2, 'analbuminæmic' serum 1/1 ; 3, normal human serum 1/100 ; 4, 'analbuminæmic' serum 1/1 containing normal human serum 1/100

Lohss and Kallee[3] have reported that 'analbuminæmic' serum may contain material behaving serologically as serum albumin, but differing from authentic serum albumin in its behaviour after extraction with a trichloroacetic acid-acetone mixture. To decide whether authentic serum albumin was present in the serum under study, the general method used by Lohss and Kallee was modified and extended. The proteins in the serum fraction where albumin might be present were radio-iodinated ; they were then precipitated with anti-human serum albumin in the presence of unlabelled carrier human serum albumin ; the antigen–antibody precipitate was dissociated with trichloro-acetic acid–ethanol ; and the protein so obtained was subjected to electrophoresis in starch gel.

The 22 per cent w/v sodium sulphate supernatant from 1·85 ml. serum was iodinated with iodine-131 by the iodine chloride method of McFarlane[4], after preoxidation of any free —SH groups with non-radioactive iodine. An authentic sample of crystallized human serum albumin was iodinated in the same way for use in parallel control tests. Although the preparation from the 'analbuminæmic' serum contained 23 mgm. protein, less than 0·1 mgm. was expected to be albumin. In order to diminish losses due to adsorption, 2 mgm. of unlabelled carrier human serum albumin was added to the labelled 'analbuminæmic' material and to 0·1 mgm. of the control human serum albumin labelled with iodine-131. The albumin in each was precipitated with 26 mgm. rabbit anti-human serum albumin in the presence of 5 mgm. potassium iodine. As is shown in Table 1, the precipitate contained only 1·1 per cent of the radioactive proteins in the test material. Even this could be partly due to co-precipitation of a part of the other labelled proteins present.

After washing the test and control precipitates twice with 0·9 per cent sodium chloride at 2°, they were stirred with 6 ml. 1 per cent w/v trichloracetic acid in 96 per cent v/v ethanol at 0°, to extract the albumin. After 2 hr. the residual precipitate was spun down at 0°, and the supernatant fluid was treated with 2 volumes of cold dry ether to precipitate the extracted protein. The recovered protein was dissolved in 1 ml. water at 0°. In this way 75 per cent of the radioactivity was recovered from the antigen–antibody precipitate prepared with authentic human serum albumin, but only 19 per cent from that prepared with the 'analbuminæmic' material. Since the bulk of the precipitate in each case was due to unlabelled carrier human serum albumin, and each sample was subjected to identical procedures, the low recovery of radioactivity from the 'analbuminæmic' material must have been due to the presence of

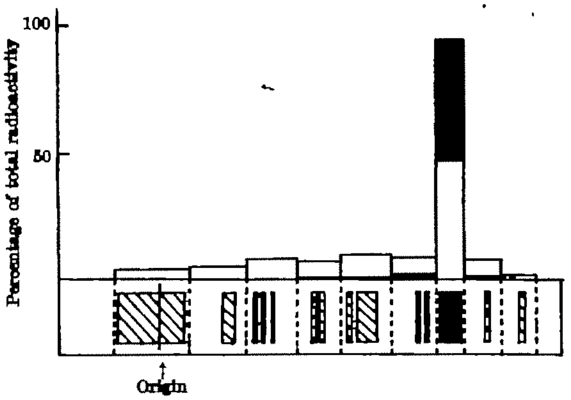

Fig. 2. Distribution of radioactivity after electrophoresis in starch gel of material recovered from analbuminaemic serum and from authentic human serum albumin. The abscissa is a diagrammatic representation of the stained gel, illustrating the position of the cuts
☐ – radioactivity in analbuminaemic material; ■ – radioactivity in authentic human serum albumin

labelled contaminants other than albumin in the precipitate.

In order to identify the recovered labelled materials definitely as human serum albumin, 0·1 ml. of unlabelled human serum was added to each, the solutions were concentrated 5–10-fold by dialysis against 'Carbowax' in the cold, and 50 µl. of each was then subjected to electrophoresis in starch gel, according to Smithies[5]. The gels were fixed and stained; the albumin had travelled 10–11 cm. from the origin and was well separated from pre- and post-albumins. The gel was photographed, and then cut into segments corresponding to each protein peak. Radioactivity in each segment was measured in a well-type scintillation counter, care being taken to ensure that conditions of counting were similar. The distribution of radioactivity along the gels is shown in Fig. 2. Whereas 94 per cent of the authentic radioactive human serum albumin was recovered in the albumin band, only 47 per cent of the radioactive protein recovered from the 'analbuminaemic' serum was located in this position, the remainder being distributed throughout the serum proteins.

It is not certain whether the non-albumin radioactivity was associated with denatured material or with traces of labelled globulins which had survived intact the earlier stages of purification, and which would not have been present in the authentic human serum albumin.

Table 1

Experimental stages	Per cent of original radioactivity recovered HSA	'Albumin' fraction of serum
Precipitated with antibody	99	1·1
Extracted with TCA-ethanol and re-precipitated with ether	75	0·208
Present in albumin peak after starch gel electrophoresis	70·5	0·098

When compared with the authentic human serum albumin labelled with iodine-131, only 0·098 per cent of the original iodinated protein in the 22 per cent sodium sulphate supernatant behaved as human serum albumin throughout the successive stages of precipitation with anti-human serum albumin, extraction in trichloracetic-acid ethanol (TCA), and starch gel electrophoresis (Table 1). On the assumption that all the proteins in the 22 per cent sodium sulphate supernatant were iodinated to the same extent, this would imply that the original serum contained 1·23 mgm. authentic human serum albumin/100 ml.—a value quite close to the 1·6 mgm./100 ml. obtained by immunochemical methods. It is not clear why these results differ from those of Lohss and Kallee[3], but the explanation may lie in pre-oxidation of —SH groups before iodination with iodine-131 or in the use of carrier human serum albumin. The results certainly underline their warning that no single technique should be relied on to identify and measure unequivocally a material constituting so small a proportion of a mixture, unless it possesses some readily identifiable specific property such as enzyme activity.

The evidence seems sufficient, however, to permit the conclusion that traces of human serum albumin were present, and that the failure of these subjects to develop antibodies in response to albumin administration does not require postulation of prolonged persistence of a state of immunological tolerance. Furthermore, it seems possible that 'analbuminaemia' may resemble 'agammaglobulinaemia' in being a condition in which there is a very great, rather than an absolute, deficiency of the particular plasma protein. This work was made on serum from a single subject, and it is clearly desirable—though impossible in this instance—to examine by similar techniques the sera from other such subjects before any transfusions have been given.

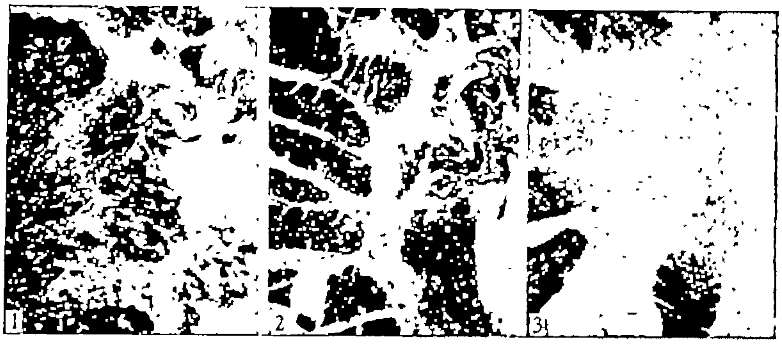
ACTION OF SOME SURFACE-ACTIVE COMPOUNDS ON THE GASTRO-INTESTINAL MUCOSA

By Dr. J. A. NISSIM
Pharmacology Department, Guy's Hospital Medical School, London, S.E.1

IN a previous article[1], the actions of trimethylhexadecylammonium stearate (cetyltrimethylammonium stearate) on the gastro-intestinal mucosa were described. These actions included: (1) damage to gastro-duodeno-jejunal mucosa after large oral and parenteral doses; (2) loss of weight, presumed to be due to functional inhibition of the gastro-intestinal mucosa, after smaller oral doses; and (3) occasional hypertrophy of the gastro-duodeno-jejunal mucosa after prolonged administration of doses that are just



Figs. 1–3. Damage with hæmorrhage in gastric and intestinal mucosa of mouse 16 hr. after a subcutaneous injection of 0·1 gm. cetrimide per kgm. body-weight. (× 86) (1) Pyloric mucosa. (2) and (3) Intestinal mucosa. Note dense altered hæmoglobin pigment at tips of villi in (2)

too small to cause loss of weight. In a preliminary investigation of the mode of action, a number of related compounds have been studied and an attempt made to relate structure and activity.

Trimethylhexadecylammonium stearate is a cationic surface-active quaternary ammonium compound practically insoluble in water. The present investigation includes the study of (1) sodium stearate and cetyltrimethylammonium bromide or cetrimide, two compounds which represent the acidic and basic parts of the molecule; (2) domiphen bromide, sodium lauryl sulphate, sorbitan monostearate ('Span 60') and polyoxyethylene sorbitan mono-oleate ('Tween 80'), of which the first two are cationic and anionic and the last two non-ionic surfactants; and (3) tetraethylammonium bromide and hexamethonium chloride, two simple quaternary ammonium compounds. In preliminary screening tests, these compounds were given by subcutaneous or intraperitoneal injection to adult male mice in order to find out which of them possessed the selective activity exhibited by trimethylhexadecylammonium stearate on the gastro-intestinal mucosa. Afterwards, some of these substances were incorporated in diet 41 in various concentrations and fed to mice, each of the animals receiving 5 gm. of diet a day. All the mice used were from non-interbred albino C stock. Tissues for histological study were only taken from animals killed when moribund.

Cationic Compounds

Cetrimide. Some of the results obtained after subcutaneous injections of cetrimide are given in Table 1. The *LD*50 of the bromide ester administered by this route was some ten times smaller than that of the stearate. There was always brown staining at the site of injection. After the smaller doses, mice died in 1–5 days and invariably showed reddish brown or coffee-ground hæmorrhages in the pyloric part or the whole of the stomach, in the duodenum, jejunum and sometimes the ileum, but not in the cæcum or colon (Figs. 1–3). Mice receiving the larger doses of cetrimide died in a matter of minutes or hours and failed to show gastro-intestinal hæmorrhage; but the duodenum was intensely stained with bile and the intestines contracted.

These findings, noted after doses of 0·25–1·0 gm./kgm., and the occasional occurrence of convulsions with varying degrees of auriculo-ventricular block, were considered compatible with an acetylcholine effect. This was confirmed by studies on the blood pressure of the cat and on the motility of strips of rat intestine. In both biological tests the potency of cetrimide was about 10^{-3} or 10^{-4} of that of acetylcholine, but the drug seemed to block itself rapidly.

Surviving animals were killed some 2–3 months after the injection and carefully examined, but no abnormality was ever detected.

When cetrimide was given intraperitoneally in doses of 0·075 gm./kgm., death occurred with convulsions within 3–5 min., but even doses of 2 mgm./kgm. caused 100 per cent mortality in about 12–15 hr. The largest doses which mice survived were 1·5 and 1 mgm./kgm., and thus cetrimide was some 50 times more toxic by the intraperitoneal than by the subcutaneous route. For the stearate ester the corresponding factor was about 10.

When cetrimide was administered orally in diet 41, however, it proved no more toxic than trimethylhexadecylammonium stearate (Table 2). It seemed unlikely that this result was due entirely to poor absorption of the cetrimide from the alimentary canal, so that inactivation of the compound by gastro-intestinal juices and/or food was presumed to occur. The ratio of intraperitoneal to oral activity was of the order of 2,000 : 1.

Domiphen bromide. This substance was administered by subcutaneous injection only (Table 1). Its *LD*50 was about 0·125 gm./kgm., or 5/3 that of cetrimide. All postmortem findings, including the histological changes in the gastro-intestinal mucosa, were similar to those after cetrimide.

Anionic Compounds

Sodium stearate. Given both subcutaneously and intraperitoneally in single doses of 0·5 and 1·0 gm./kgm., this compound was distinctly devoid of

	2·00	6	27·4	19·5	− 7·9	3–4

any adverse effect on the thirteen animals used, and no loss of weight was noted. When killed 1–2 months after the injection, these mice differed in no way from the controls. The substance was also given to 16 animals in a concentration of 0·5, 1, and 5 per cent in diet 41. The results leave no doubt that for all practical purposes the gastro-intestinal activity of trimethylhexadecylammonium stearate is invested entirely in the cationic part of the molecule.

Sodium lauryl sulphate. Subcutaneous doses of 0·1, 0·2, 0·5, 1 and 2 gm./kgm. of this compound were each given to two mice. Large skin ulcers, at first surrounded by oedema, appeared in the same day after the injection of the largest three doses. The ulcers did not perforate to the peritoneum, which was evidently resistant to this action, and there was no evidence of systemic disturbance after the injection. The animals remained alive and well and the ulcers healed in about six weeks. Intraperitoneal injections of 0·2 and 0·4 gm./kgm. were each given to four mice. The animals receiving the larger dose died within 1–3 days, but postmortem revealed no consistent pathological abnormality to indicate the cause of death.

The results obtained with oral feeding of sodium lauryl sulphate in concentrations of 0·5, 1 and 2 per cent are of fundamental importance. Death supervened within four days in the group receiving the highest concentration, and all six animals showed typical gastro-intestinal hæmorrhage associated with marked loss of weight, just as in the case of cetrimide and domiphen. However, the toxic dose was critical, as no adverse effects were noted after the two smaller concentrations of 0·5 and 1 per cent even in experiments lasting some three months. Animals receiving 1 gm./kgm. of this drug showed a transient loss of weight averaging 2 gm. per mouse at five weeks.

Non-Ionic Compounds

Both sorbitan monostearate ('Span 60') and polyoxyethylene sorbitan mono-oleate ('Tween 80') were given as a 10 per cent aqueous suspension and solution respectively by subcutaneous injection to mice in doses of 1, 4 and 8 gm./kgm. No loss of weight followed, the animals remained healthy, and nothing abnormal was found when the animals were killed four weeks later. Doses of 1 gm./kgm. of 'Tween 80' given by stomach tube to three mice did not cause gastro-intestinal hæmorrhage.

Simpler Quaternary Ammonium Compounds

Tetraethylammonium bromide and hexamethonium chloride were tested in subcutaneous doses ranging from 20 to 200 mgm./kgm. The animals either died in 10–60 min. and failed to show any injury to the gastro-intestinal mucosa or survived the dose and showed nothing abnormal when killed a week later.

Discussion

The above results indicate clearly that the activity of trimethylhexadecylammonium stearate with regard to the gastro-intestinal mucosa is invested mainly, and may be entirely, in the cationic part of the molecule. The related substance domiphen bromide possesses the same effect. If the side-chain of the quaternary ammonium compounds is shortened or removed, this activity is abolished. It is possible, however, that such an effect is still invested in the quaternary ammonium structure and may be revealed by investigating less-soluble esters of the compounds, for example, tetraethylammonium stearate. The fact that this action on the gastro-intestinal mucosa may also result from the administration of the non-quaternary-ammonium anionic sodium lauryl sulphate strongly suggests that the activity is a feature of an ionic (cationic or anionic) long-chain structure, particularly as the non-ionic compounds tested gave entirely negative results.

A point of great interest is that in the case of sodium lauryl sulphate the gastro-intestinal effect disappeared completely when the dose was reduced from 2 to 1 gm./kgm. In other words, with this compound the effect appears abruptly and maximally at a critical dose. In the case of the cationic quaternary ammonium surfactants, the range of activity was at least 2–3 times that of sodium lauryl sulphate, so that halving a maximally toxic dose twice did not abolish the effect. The fact that such gradation in activity is possible is a useful indicator for future research, since an even greater grading of response may be expected to be associated with decreased toxicity.

REDUCTION OF THE INTESTINAL ABSORPTION OF GLUCOSE, METHIONINE AND SODIUM BUTYRATE BY THE CATION TRIMETHYLHEXADECYLAMMONIUM

By Dr. J. A. NISSIM

Pharmacology Department, Guy's Hospital Medical School, London, S.E.1

IN two preceding publications[1] it was shown that some ionic surface-active compounds, including the stearate and bromide of trimethylhexadecylammonium, have definite structural effects on the gastro-intestinal mucosa. Interference with the absorptive function of the intestine was also presumed. In this article an account is given of the effect of these compounds on the intestinal absorption of glucose, methionine, sodium butyrate and water, as studied in more direct experiments.

The methods used in the study of the effect of the trimethylhexadecylammonium cation on intestinal absorption are convenient modifications of the method described by Jervis *et al.*[2]. The different nutrient substances were perfused in normal saline, with or without the drug, through the intestine of rabbits or albino rats and circulated by a flow of moist oxygen from a cylinder. The animals were anæsthetized with sodium pentobarbitone, the gut washed with warm saline and emptied. A length of small intestine consisting of the duodenum plus a piece of jejunum, about 2 ft. long in the rat and 3 ft. long in the rabbit as measured from the duodeno-jejunal flexure, was perfused with a known volume of the fluid under study. At the end of each experiment the perfusate was drained into a flask, its volume measured, and the amount of fluid absorbed or secreted per hour calculated. The length of the perfused intestine was then removed and measured accurately. From the difference between the initial quantity of each of the substances perfused and the final amount recovered, the percentage absorption was calculated.

The different solutions used were approximately neutral, their *p*H values ranging from 6·7 to 7·7.

Glucose was estimated by the modified Schaffer–Hartman method of King[3], methionine by the method of McCarthy and Sullivan[4], and sodium butyrate by the method of Smyth and Taylor[5]. Perfused and non-perfused duodenum and jejunum were fixed either in formol-saline or in ice-cold 80 per cent alcohol at the end of the experiment for histological study.

The experiments may be divided into two groups according to duration of perfusion: 2-hr. perfusion experiments, and half-hour perfusion experiments.

Two-hour Perfusion Experiments

The control perfusion fluid consisted of normal saline containing either 0·3 per cent glucose and 0·3 per cent methionine together or 0·3 per cent sodium butyrate alone. 250 and 125 ml. of fluid were perfused in the case of rabbits and rats respectively. Trimethylhexadecylammonium stearate was added to the perfusion fluid to give concentrations of 0·1 and 0·5 per cent, while cetrimide was used in concentrations of 0·01 and 0·1 per cent. Samples of perfusate for glucose and methionine, or butyrate estimations, and samples of blood for glucose estimations were taken at 0, 1 and 2 hr. Perfusion pressure was 10–12 cm. at the duodenal end, but only just above zero at the distal end. The rate of flow was kept at 20–40 ml./min. by adjusting the oxygen flow. The bile duct was included in some experiments and excluded in others.

Rats. This group comprised four control rats and eight rats perfused with the control solution containing the drug in the form of the stearate ester. Four of the latter received 0·1 per cent and four received 0·5 per cent of the drug, but since the results obtained with the two concentrations did not differ significantly, they have been grouped together for simplicity (Table 1, Fig. 1). The absorption of glucose and of methionine fell to one-half and one-third respectively with the addition of the drug, and the absorption of water was likewise diminished. Furthermore, in spite of wide variations in the levels of blood sugar under the conditions of the experiment, there was a net rise of 32 mgm./100 ml. in the control group and a net fall of 6 mgm./100 ml. in the treated group, a result compatible with the more rapid rate of absorption of glucose in the former. To counter the suggestion that the decreased rate of disappearance of glucose from the perfusate under the influence of the drug was due to decreased utilization by intestinal bacteria, a suspension of some 15–20 per cent of the intestinal contents of a rat in 125 ml. of the control solution was circulated in the apparatus for 2 hr.,

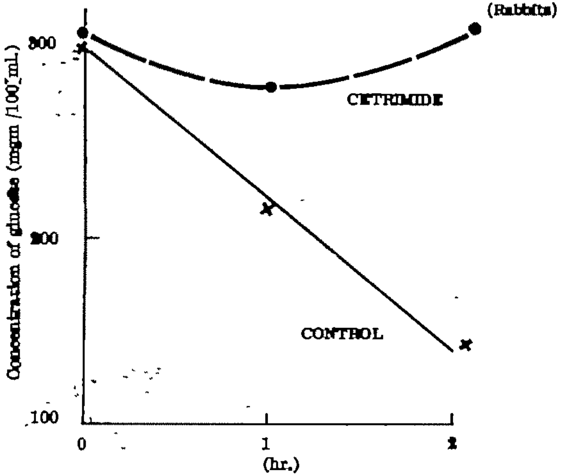

Fig. 2. Curves showing rate of disappearance of glucose from perfusate in nineteen control rabbits and six rabbits receiving 0·1 per cent cetrimide in 2-hr. perfusion experiments

but no measurable change was noted in the glucose concentration at the end of the experiment.

Rabbits. This group comprised initially nine control rabbits. The perfusion of 0·1 per cent trimethylhexadecylammonium stearate in seven rabbits, with and without 0·06 per cent hydrochloric acid or bile, did not inhibit the absorption of either glucose or methionine. Similarly, the perfusion of 0·01 per cent cetrimide in three rabbits had no effect. These 10 rabbits were therefore included in the final control group, which now comprised 19 experiments. Six rabbits were then given 0·1 per cent cetrimide in the perfusion fluid, and here the results as regards glucose absorption were striking, but the absorption of methionine remained unaffected. In three of the six rabbits the glucose titration readings were in fact greater for the final sample than for the first, and if the reducing material is accepted as wholly glucose, the excess sugar recovered in the perfusate equalled 125, 159 and 212 mgm. respectively, so that in the last hour the direction of net flow of glucose was from the blood to the intestine (Table 1, Fig. 2).

Three control rabbits were given 0·3 per cent sodium butyrate in normal saline but no glucose, and three were given the same solution containing 0·1 per cent cetrimide. There was no inhibition of the absorption of the short-chain fatty acid as is evident from Table 1, but although no glucose could be demonstrated in the perfusate of the control rabbits at any time, reducing material began to appear at 1 hr. in the perfusate of the rabbits receiving cetrimide and the total recovered at 2 hr. for the three rabbits was equivalent to 220, 306 and 391 mgm. glucose.

Finally, in one experiment, 0·1 per cent glucose-free solution of cetrimide in normal saline was perfused in a rabbit for 6 hr. Titration readings for glucose on the perfusate gave the values of 0, 23, 75, 104, 116, 122 and 133 mgm./100 ml. at 0–6 hr. The 2-, 4- and 6-hr. values of 75, 116 and 133 mgm./100 ml. were checked by the specific glucose oxidase method of Huggett and Nixon[8], and the respective values 80, 108 and 127 mgm./100 ml. were obtained. The close agreement between the two sets of figures identifies the reducing substance as mainly if not entirely glucose.

125 and 250 mgm. cetrimide given subcutaneously to two rabbits, both weighing 2 kgm., did not cause glycosuria, so that in comparable doses this substance does not appear to possess the obvious blocking effect of phloridzin on the absorption of glucose by the renal tubules. Conversely, a perfusion experiment in which 0·1 per cent phloridzin was used reduced the intestinal absorption of glucose only to 25 per cent and had no effect either on methionine or on butyrate absorption.

Half-hour Perfusion Experiments

Only rats were used here, and the perfusion fluid consisted of 50 ml. of normal saline containing 0·2 per cent each of glucose, methionine and sodium butyrate, which were studied together. The drug concentrations were the same as in the 2-hr. experiments. Blood samples were collected from the tail at the beginning and end of each experiment, and the change in blood sugar noted; but perfusate samples were estimated for sugar, amino-acid and fatty acid only at the end. The hydrostatic pressure was kept at 7–10 cm. at the duodenal end, and the rate of flow at 10–20 ml./min. The bile duct was included in all experiments.

TAS = Trimethylhexadecylammonium stearate.

The results obtained in five groups of four rats are given in Table 2. The five groups comprised a control group and four others in which the animals received in addition 0·1 and 0·5 per cent of the stearate ester and 0·01 and 0·1 per cent of the bromide ester in the perfusion fluid. The effect of the cationic trimethylhexadecylammonium of both esters on the absorption of water, glucose, methionine and butyrate can scarcely be questioned.

In all experiments with this cation the secretion of mucus by the intestine was increased as compared with the control, and the effect seemed proportional to the activity and concentration of the drug.

Histological Results

In 2-hr. perfusion experiments, both in control and treated animals, large numbers of cells appeared in the lumen of the gut and consisted chiefly of leucocytes and shed epithelial and mucus cells; but, in addition, rabbits perfused with 0·1 per cent cetrimide showed definite damage to the intestinal villi. In half-hour perfusion experiments, the number of cells in the lumen was markedly less and scarcely differed from non-perfused control intestine. Similarly, rats perfused with 0·1 per cent trimethylhexadecylammonium stearate did not differ significantly from either, but those perfused with 0·5 per cent of the stearate ester and with 0·01 per cent of the bromide ester showed a significant increase in cells shed and those receiving 0·1 per cent cetrimide showed frank damage to the intestinal mucosa (Figs. 1–3).

Discussion

The most striking and consistent effect of trimethylhexadecylammonium was on the absorption of glucose, which at a concentration of 0·1 per cent of the bromide ester appeared to be completely inhibited. At this concentration cetrimide is described as non-irritant to tissues[7]; however, the injury to the intestinal villi in these experiments was unmistakable. An interesting feature was the marked differences in species with regard to their sensitivity to the inhibitory action on glucose absorption. There was, in addition, the interesting absence of an inhibitory effect on the absorption of methionine and sodium butyrate in the rabbit, though the effect on the absorption of glucose was more or less as pronounced as in the rat. Furthermore, it is evident that the inhibitory effect on absorption was not related to the degree of injury caused by high concentrations of this cation, as the absorption of methionine and butyrate continued at high concentrations in the rabbit, but failed at low concentration in the rat. This is an important finding, and in the search for new compounds the aim should be to widen this gap still further.

The results of perfusion experiments reported here support the earlier conclusion[1] that large doses lead to structural damage, while small doses "appear to reduce the functional efficiency of the mucosal cell". The functions of the mucosal cells are presumed to be mainly enzymic in nature. In the present investigation, the marked species differences point clearly to specific enzyme actions being involved in the functional inhibition of activity.

The concentrations of the stearate ester used in the perfusion experiments have been of the same order as those used in feeding experiments, but in assessing the significance of histological injury to the intestinal mucosa it should not be assumed that the same conditions prevail for the action of the drugs in both cases. It is quite clear, for example, that cetrimide in the rat is at least ten times and probably a hundred times as active in perfusion as in feeding experiments in which the drug is incorporated with diet 41. It is possible that the inhibition of absorption, which in all probability depends on the uptake of the cation by specific enzymes, can be achieved slowly in a feeding experiment as the ester is gradually solubilized in the intestine to inactivate more and more enzyme molecules. On the other hand, structural damage of villus cells, which evidently differs in its mechanism from that of inhibition of absorption, may be more directly related to the actual concentration of the cation present in the bathing fluid.

I should like to thank Mrs. Miriam Thurlow and Miss Myra Jones for their expert and willing technical assistance, Mr. L. Westwood for invaluable help, particularly in the preparation of the histological sections, and Prof. W. J. H. Butterfield and Miss Margaret Wichelow for carrying out check glucose estimations by the oxidase method.

PHYSICS

Effect of a Resisting Couple on the Rotational Motion of a Rigid Body

THE examination of the effect of external couples upon the rotational motion of artificial Earth satellites has been of interest, in view of the rapidity with which their instantaneous axes of rotation have been observed to approach the axis of greatest moment, even when they have been initially spun about the axis of least moment. In this particular problem the role of internal energy dissipation due to non-rigidity may in fact be important, but, setting this aside, the theorem set out below appears relevant. This states a well-known principle and many of its corollaries have been proved; however, I have been unable to trace any direct reference to the proposition, or its converse, and would be grateful if any reader could do so.

The proposition is as follows. An external couple applied for a discrete time to a rigid body about its instantaneous axis of rotation in the sense opposing its rotation tends to cause that axis to approach the axis of greatest moment (provided that the instantaneous axis is not initially that of a permanent rotation).

In regard to the proof, we note that if **h** is the vector moment of momentum, and **w** the angular velocity, then the kinetic energy of the rotation is:

$$T = \tfrac{1}{2}\mathbf{h}.\mathbf{w} \qquad (1)$$

and in the free motion following the application of the couple, the invariable line intersects the surface of the ellipsoid of gyration at points distant $(h^2/2MT)^{1/2}$ from its centre (M being the body mass). Thus the value of $(h^2/2T)$ is bounded above and below by the greatest and least moments of inertia, and such limit values denote respectively a permanent rotation of the body about the axes of greatest and least moment in the free motion. Further, within these bounds, an increase in $(h^2/2T)$ would imply a change in the free motion consisting of an expansion of the invariable cone about the axis of least moment, and/or a contraction about that of greatest moment. The corresponding change in configuration of the polhode cone is analogous, as it is an affine transformation of the invariable cone.

Interpreting such a change in the motion to be that implied in the theorem, its proof is as follows. From the equations of motion we deduce that, if G is the couple, then during its action:

$$\mathbf{w}.\mathrm{G} = \frac{\mathrm{d}T}{\mathrm{d}t} \qquad (2)$$

$$2\mathbf{h}.\mathrm{G} = \frac{\mathrm{d}h^2}{\mathrm{d}t} \qquad (3)$$

Consequently it follows from (2) and (3) that:

$$T^2 \frac{\mathrm{d}}{\mathrm{d}t}(h^2/T) = 2T(\mathbf{h}.\mathrm{G}.) - h^2(\mathbf{w}.\mathrm{G}.)$$

or using equation (1), the right-hand side may be rearranged to give:

$$\left.\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}(h^2/2T) &= \tfrac{1}{2}(\mathrm{G}\times\mathbf{h}).(\mathbf{h}\times\mathbf{w})/T^2\\ &= \tfrac{1}{2}[\mathrm{G},\mathbf{h},\mathbf{h}\times\mathbf{w}]/T^2\end{aligned}\right\} \qquad (4)$$

If, as in the proposition, G is opposite to **w**, then $(h^2/2T)$ is increased while the couple acts and remains constant thereafter, unless $\mathbf{h}\times\mathbf{w} = 0$, which would indicate a rotation about a permanent axis. It may further be shown that the value of $(h^2/2T)$ increases asymptotically to its upper bound as the total applied wrench is indefinitely increased.

The converse of the theorem may be stated as follows. If the instantaneous axis, not being initially permanent, is caused to approach the axis of greatest moment by the action of an external couple, then for some discrete time the resolved component of that couple about the instantaneous axis opposes the motion.

For we may, without loss in generality, compound the couple of three non-planar components, one in the direction of the vector $\mathbf{h}\times\mathbf{w}$ (which exists if the instantaneous axis is non-permanent), another in the direction of the moment of momentum and one in the direction of the instantaneous axis. By (4), only the last-named component affects the rate of change of $(h^2/2T)$, and since $(h^2/2T)$ is increased, this component must be sensed in opposition to **w**.

Thus, the instantaneous axis of rotation of a rigid body, not being initially a permanent axis, approaches the axis of greatest moment if, and only if, the body is acted on for some discrete time by a resisting couple about the instantaneous axis. A body subjected to a continuous resisting couple about the instantaneous axis is unstable in an initial motion about the permanent axis of least moment, but stable about that of greatest moment.

An exactly analogous proposition and converse exists in relation to an accelerating couple, the body then tending to rotate about the axis of least moment.

A Relation between Ultra-sonic Velocity and Latent Heat of Vaporization

SEVERAL attempts have been made by different investigators to find the relation between ultra-sonic velocity in liquids and the physical properties. One such relation has been obtained by Rao[1] empirically. Recently, Kishimoto and Nomoto[2] have obtained a relation between temperature coefficient of ultra-sonic velocity and boiling point of a liquid. In this communication we present a new relation between ultra-sonic velocity and latent heat of vaporization.

For this investigation we have used ultra-sonic velocity data taken from the literature for about

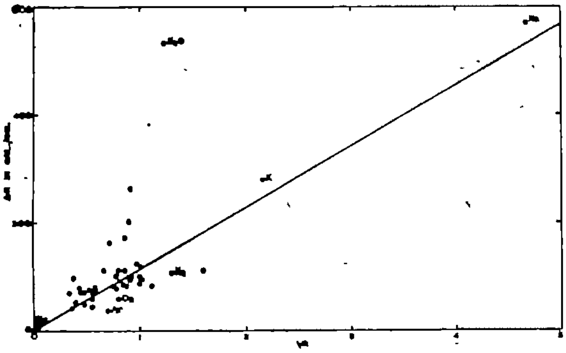

Fig. 1. Relation between ultra-sonic velocity and heat of vaporization

forty-five liquids in addition to some measurements which we have made on liquids not included in the literature. We have included a few liquefied gases and molten metals. In the first instance the values of the latent heats of vaporization L_v were plotted against the ultra-sonic velocities at 30° C., but as there was no sign of linearity in the graph, the values of L_v were replotted against the square of the ultra-sonic velocity V. It was found that the observations gave a fairly linear graph. To see if the linearity of the plot of points improves, the values of the latent heats at boiling point are again plotted against the extrapolated ultra-sonic velocities at temperatures where the molar volume of the saturated vapour of the liquid is 22·4 l., and this plot (Fig. 1) shows a better degree of linearity. A smooth line is drawn so as to pass through the maximum number of points, and using the gradient of this straight line the following empirical relation is obtained:

$$L_v = 133\,V^2$$

where L_v is in cal./gm. and V in km./sec. If L_v is expressed in ergs/gm. and V in cm./sec., this relation reduces to the simple form $L_v \approx \frac{1}{2}V^2$.

It may be noted that significant deviations from the linear graph are observed only in the case of highly associating liquids like water, alcohols and organic acids. It is in any event expected that these liquids would not show such a simple relation in view of the molecular associations and complexes formed. It is significant that these deviations are always on the higher side of L_v as expected, and the excess over the value from the linear graph may be regarded as giving some idea of the association energy.

We have been able to deduce this relation theoretically by using the equation of state of a liquid obtained by Wentorf, Buehler, Hirschfelder and Curtiss[3] based on Lennard-Jones and Devonshire's liquid model[4], and utilizing also Trouton's rule modified by Hildebrand and the relations deduced by Kishimoto and Nomoto[2]. A detailed paper embodying these results will shortly be published elsewhere.

We are indebted to the Council of Scientific and Industrial Research for financial assistance in this research work.

CRYSTALLOGRAPHY

Macroscopic Swelling of Vermiculite Crystals in Water

EXPANDING lattice-layer silicates belonging to the smectite and vermiculite groups form complexes with organic cations by replacement of the inorganic cations normally present in interlayer positions in these minerals[1-4]. The formation of a complex, and sometimes also the orientation of the organic ions within the lattice, can be inferred from changes in the basal spacing of the mineral as shown by X-ray diffraction.

During studies of a series of vermiculite-organic complexes, it was observed that single crystals of vermiculite containing interlayer butylammonium ions swell macroscopically when placed in water. Swelling is anisotropic and occurs in a direction perpendicular to the plane of the silicate layers, leading to an increase in volume of the order of 3,000 per cent. The swollen crystals are coherent and gel-like. Their shape and homogeneous appearance suggest that the 10-Å. thick silicate layers remain effectively parallel to one another on swelling, and the observed increase in thickness indicates a mean interlayer distance of several hundred angstroms. Low-angle X-ray diffraction examination of several swollen crystals, for which I am indebted to Drs. K. Norrish and J. A. Rausell-Colom, indicates that individual interlayer distances probably do not deviate markedly from the mean value.

In view of these results, it seems justifiable to derive the interlayer distance in swollen crystals directly from measurements of the change in thickness of a crystal before and after swelling. The data in Fig. 1 were calculated on this basis using a vermiculite from Kenya[7], and show that the swelling, which is reversible, can be controlled by varying the concentration of butylammonium ions in the external solution. At high concentrations, the interlayer distance is 9–10 Å. (d_{001} = 19·2 Å.), suggesting that the butylammonium ions are oriented at right angles to the silicate layers. When the external concentration is reduced to about 0·06 N, marked swelling develops rather suddenly, and spacings in the region of 170 Å. are found. Further dilution results in continuous swelling to a maximum of about 530 Å. at infinite dilution. In this latter region, the interlayer distance appears to be related linearly to the reciprocal of the square root of solution concentration.

The ability of single crystals of lithium-vermiculite to swell when immersed in water has been mentioned briefly on previous occasions[8,9]. Tests show that the

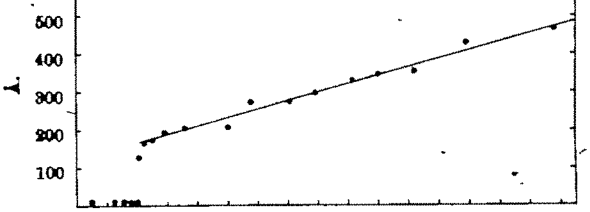

Fig. 1. Relationship between interlayer distance of butylammonium-vermiculite and concentration of butylammonium chloride in external solution (C = moles/litre)

degree of swelling in this system is also related to electrolyte concentration, but a tendency for the lithium-vermiculite crystals to exfoliate and break along cleavage planes during swelling makes measurements of changes in crystal thickness less reliable as an index of interlayer distance. Nevertheless, the indications are that, while the maximum amount of swelling is of the same order as that observed with butylammonium-vermiculite, the discontinuity in the curve, which occurs at about 0·15 *N* in this instance, leads to a relatively small 'step' of a few tens of angstroms. Apart from lithium and butylammonium, no other inter-layer ions tested so far cause extensive macroscopic swelling with water, although propylammonium ions produce limited swelling in certain vermiculites.

The swelling process in lithium-vermiculite recalls the swelling of aggregates of hydrogen-, lithium- and sodium-montmorillonites as studied by Norrish[9], and ascribed to the development of diffuse electrical double layers following upon the hydration and dissociation of the cations from the negative sites on the silicate layer surfaces. One may speculate that a similar mechanism operates in the butylammonium-vermiculite system, and that the sudden large expansion to an interlayer distance of 170 Å. at 0·06 *N* electrolyte concentration corresponds with the formation of 'icebergs'[10] around the butylammonium ions.

The highly oriented structure of these swollen crystals appears to offer a unique opportunity for examining the properties of water films of variable and known thickness associated with silicate layer surfaces, and further work on this and other aspects of these systems is in progress.

Dislocations in Layer Structures

Amelinckx and Delavignette[1] have recently studied non-metallic substances with layer structures, including talc and graphite, by transmission electron microscopy. They observed nets of widely dissociated dislocations particularly in talc. Splitting into more than two partial dislocations in such hexagonal layer substances had been forecast by Kronberg[2]. Grenall[3] has observed dislocations in graphite previously, but did not observe dissociation into partials.

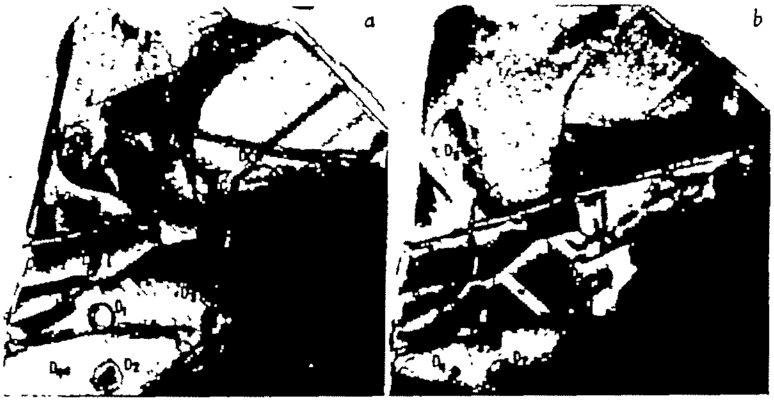

Fig. 1(*a*). Transmission electron micrograph of molybdenite flake. (*b*) As (*a*), but sample tilted about 1°. (× 62,000)

We have examined cleavage fragments of graphite and molybdenite for evidence of dislocations and have found that the interpretation of electron micrographs from such materials is rendered difficult by the presence of contrast effects due to extraneous surface detail such as steps and irregularities and by the presence of sub-grain boundaries. However, if a massive specimen is split in two, very thin and quite uniform leaflets can usually be found on the cleavage surfaces. Suitable leaflets of molybdenite which transmit in the red can be selected under the microscope using indirect illumination, and freed from the bulk with a fine needle. These specimens (about 1 cm. × 1 cm. × 1μ) are adequate for optical transmission studies[4], but are found still to consist of somewhat misoriented aggregations of sub-grains. When such specimens are exposed to ammonia vapour at − 78° C., a rapid absorption takes place, which results in a considerable weakening of the solid, so that these already thin pieces disintegrate easily into thinner fragments without undue mechanical damage. Fragments obtained in this way give reasonably interpretable results when submitted to transmission microscopy at high resolution in a Siemens 'Elmiskop I' electron microscope using 100 kV. Figs. 1*a* and *b* are an electron stereopair (tilt angle, 1–2°), obtained on molybdenite, which show a number of interesting features. A network of dislocations running vertically and spaced about 100 Å. is visible at *A* in Fig. 1*a* and disappears on tilting (Fig. 1*b*). A number of dislocations are visible at *B* (Fig. 1*b*). The prominent looped line feature at *C* in Fig. 1*a*, the contrast of which decreases in Fig. 1*b*, is probably also a dislocation. A number of interesting closed loops are visible at *D* in Figs. 1*a* and *b*. On tilting, some of the loops tend to change from single to double loops as at D_1; others show contrast reversal within the loop, as at D_2 and D_3. Loops with a dark centre spot are also observed at D_4 and D_5. The loops showing contrast reversal are thought to be dislocation loops enclosing stacking faults, although the details await further elucidation. Cleavage steps are visible at *E* (Fig. 1*a*).

Graphite flakes prepared by the above technique have not so far yielded results of similar interest, but recently we obtained a spectrographic graphite powder of high purity and a remarkable degree of order (grade *SP1*, National Carbon Co., New York, N.Y.). This material can be packed under moderate compression to give compacts of the density anticipated for a graphite single crystal, which is somewhat

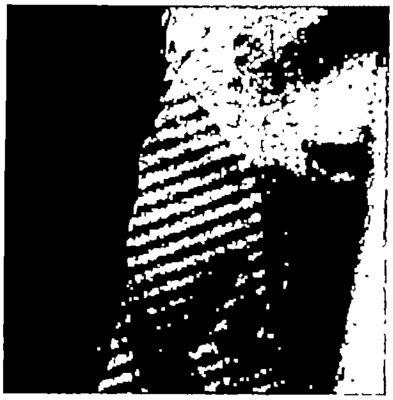

Fig. 2. Transmission electron micrograph of graphite particle. (× 62,000)

unusual. The powder consists of well-defined hexagonal particles, about 10μ wide, the edges of which are sufficiently transparent to 100-kV. electrons to permit examination at high magnification. The plate-like particles frequently show moiré fringes indicating a rotational misfit between adjacent layers, which are presumably each some hundred angstroms thick. The perfection of the moiré patterns over distances of ½–1μ (Fig. 2) indicates that regions of the layers up to this size are free from imperfection. A fourfold line detail some 600 Å. wide, which is probably a set of dislocations lying in the basal plane, may be seen running from *A* to *B* (Fig. 2), acutely inclined to the moiré fringes. A similar band of four lines can be seen running from *C* to *D*, increasing in width to a maximum of about 500 Å. as *C* is approached. Since graphite is a material of exceptionally low stacking fault energy, wide dissociation of dislocations into partials connected by stacking fault is to be expected. The two bands *AB* and *CD* are thought to consist of partial dislocations. The observation of four partial dislocations in graphite accords with the number expected from atomic considerations of the possible steps in the shear process.

A number of other features in Fig. 2 are worthy of note. *EF* is a dislocation which is roughly parallel to the band *CD* discussed above. *G* is a hexagonal loop which is about 1400 Å. long by 850 Å. wide. This is probably a dislocation loop. One pair of sides of this loop is parallel to the moiré fringes, another pair is parallel to the crystal edge *HJ*. The existence of hexagonal dislocation loops may be related to the observation by R. H. Savage (private communication) that thermal etching of graphite produces shallow hexagonal holes, and to the observation by one of us (P. C.) that chemical etching produces similar holes. Above *H*, a number of further dislocations are visible.

It appears to us that the search for dislocations in materials of this type is rewarding, but in the softer materials is very dependent on method of preparation of the sample.

CHEMISTRY

Cage Effect in the Liquid-Phase Photolysis of Fluorinated Ketones

In a previous communication[1], the products of photolysis of 1 : 3 dichlorotetrafluoroacetone were described, and the absence of compounds which could arise from the reactions of the chlorodifluoroacetyl radical noted. It is assumed that in this behaviour the ketone is similar to hexafluoroacetone, which has been shown to dissociate on photolysis into two trifluoromethyl radicals and a molecule of carbon monoxide[2]. Acetone, on the other hand, has been shown to dissociate into an acetyl and a methyl radical when photolysed at room temperature[3].

It seems probable that the primary act in the photolysis of 1 : 3 dichlorotetrafluoroacetone is the production of two chlorodifluoromethyl radicals and a molecule of carbon monoxide, although the results do not rule out the possibility of the intervention of a short-lived chlorodifluoroacetyl radical.

This work has now been extended to two more fluorinated ketones, 1 : 1 : 3 : 3 tetrachlorodifluoroacetone and 1 : 1 : 3 trichlorotrifluoroacetone, and once again no trace of products which could arise from reactions of halogenated acetyl radicals was found among the photolysis products. It is assumed that either the primary act is dissociation into two radicals and a molecule of carbon monoxide or else the life-time of the halogenated acetyl radical formed is very short.

$$CF_2ClCOCCl_2F \xrightarrow{h\nu} .CF_2Cl + .CCl_2F + CO$$

$$CFCl_2COCCl_2F \xrightarrow{h\nu} 2.CCl_2F + CO$$

The ultra-violet absorption spectra are similar to that of 1 : 3 dichlorotetrafluoroacetone.

(Trichlorotrifluoroacetone $\lambda_{max.}$ 2950–3050 Å. $\varepsilon_{max.}$ 58
Tetrachlorodifluoroacetone $\lambda_{max.}$ 2900–3050 Å. $\varepsilon_{max.}$ 48)

The photolysis products of 1 : 1 : 3 : 3 tetrachlorodifluoroacetone have been shown to contain 1 : 1 : 2 : 2 tetrachlorodifluoroethane, which arises by the combination of the two dichlorofluoromethyl radicals.

The photolysis products of 1 : 1 : 3 trichlorotrifluoroacetone, on the other hand, were shown to contain three different halogenated ethanes arising from combinations of the two different radicals formed in the primary step.

$$2.CF_2Cl \rightarrow CF_2ClCF_2Cl\,(R_1R_1) \qquad (1)$$

$$.CF_2Cl + .CCl_2F \rightarrow CF_2ClCCl_2F\,(R_1R_2) \qquad (2)$$

$$2.CCl_2F \rightarrow CCl_2FCCl_2F\,(R_2R_2) \qquad (3)$$

As in the case of 1 : 3 dichlorotetrafluoroacetone it has been found that the radicals produced in the primary act are capable of abstracting chlorine atoms from the unphotolysed ketone to yield the corresponding halogenated methanes.

$$.CCl_2F + CCl_2FCOCCl_2F \rightarrow CCl_3F + .CClFCOCCl_2F$$

$$.CCl_2F + CCl_2FCOCF_2Cl \rightarrow CCl_3F + [.CClFCOCF_2Cl \text{ or } CCl_2FCOCF_2]$$

$$.CF_2Cl + CCl_2FCOCF_2Cl \rightarrow CCl_2F_2 + [.CClFCOCF_2Cl \text{ or } CCl_2FCOCF_2]$$

With 1 : 1 : 3 : 3 tetrachlorodifluoroacetone the products of this secondary reaction are trichlorofluoromethane and a halogenated acetonyl radical, which can undergo further combination reactions.

The secondary reactions of chlorine abstraction are much more complex in the case of 1 : 1 : 3 trichlorotrifluoroacetone, for the two dissimilar radicals produced may each abstract chlorine from either end of the halogenated acetone to give dichlorodifluoromethane (R_1Cl), trichlorofluoromethane (R_2Cl) and two isomeric halogenated acetonyl radicals. The further reactions of these radicals lead to the formation of a complex mixture of halogenated ketones, propanes and butanes, most of them too involatile to be identified with the present analytical procedure. One of the propanes, 1 : 3 dichlorohexafluoropropane, however, was sufficiently volatile to be isolated and identified by a combination of gas chromatography and mass spectrometry. It has already been identified among the photolysis products of 1 : 3 dichlorotetrafluoroacetone. The mechanism of its formation is uncertain, but it may arise either as a product of the combination of difluorochloromethyl and tetrafluorochloroethyl radicals or through the intervention of a CF_2 radical.

Trotman-Dickenson[4] has pointed out that even when two radicals R_1 and R_2 are very dissimilar the ratio of their product is such that :

$$\frac{[R_1R_2]}{([R_1R_1][R_2R_2])^{1/2}} \simeq 2 \cdot 0$$

where R_1R_1, R_2R_2, and R_1R_2 are the products of reaction.

When 1 : 1 : 3 trifluorotrichloroacetone was photolysed in the gas phase the proportions of the three halogenated ethanes formed were such that this ratio was 1·9.

The irradiation with light from a high-pressure mercury vapour lamp of 1 : 1 : 3 trichlorotrifluoroacetone in the liquid phase at room temperature resulted, however, in the formation of the three halogenated ethanes in proportions such that :

$$\frac{[R_1R_2]}{([R_1R_1][R_2R_2])^{1/2}} = 2 \cdot 6$$

This result is explained on the assumption that the two unlike radicals are formed within a 'cage' of unphotolysed ketone molecules which restrict their free diffusion apart. This concept of the 'solvent cage' was first put forward by Franck and Rabinowitch[5] and has usually been invoked to explain low quantum yields on the basis of recombination within a cage. This work has been extended by Lampe and Noyes[6], who studied the recombination of iodine atoms. The kinetics of photolysis of these three ketones provide direct evidence for the existence of such an effect. In the photolysis of 1 : 1 : 3 trichlorotrifluoroacetone the radicals escaping from the cage may either combine with each other or abstract chlorine from the unphotolysed ketone. Thus the ketone provides both a physical and a chemical cage. The effect of chlorine abstraction is reduced if the ketone is diluted with a solvent from which no abstraction can take place. Thus when the ketone is mixed with an equal volume of perfluoro-2-ethylcyclohexane and photolysed, the proportions of halogenated ethanes are such that :

$$\frac{[R_1R_2]}{([R_1R_1][R_2R_2])^{1/2}} = 2 \cdot 2$$

The effect of the chemical cage is demonstrated by the addition of 1 : 1 : 3 : 3 tetrachlorodifluoroacetone, which, providing more dichlorofluoromethyl radicals, should lower the ratio. In fact, because of the greater efficiency of the symmetrical ketone as a radical scavenger, the ratio of halogenated ethanes produced is such that :

$$\frac{[R_1R_2]}{([R_1R_1][R_2R_2])^{1/2}} = 3 \cdot 9$$

The effect of the physical cage is demonstrated by the use of perfluoro*cyclo*hexane as a solvent. Solutions of 1 : 1 : 3 trichlorotrifluoroacetone in this solvent have a high viscosity and, when photolysed, smaller amounts of the symmetrical ethanes are formed so that :

$$\frac{[R_1R_2]}{([R_1R_1][R_2R_2])^{1/2}} = 2 \cdot 8$$

These results are supported by studies of the photolysis of mixtures of 1 : 3 dichlorotetrafluoroacetone and 1 : 1 : 3 : 3 tetrachlorodifluoroacetone in the liquid phase, although the situation is complicated by the fact that the rates of production of radicals are now different. After 30 min. irradiation of such a mixture no unsymmetrical ethane was formed and on prolonged photolysis the ratio gradually rose to 0·4. When the mixture was diluted with perfluoroethyl*cyclo*hexane the ratio rose to a value of unity. In these cases it is the like radicals which are confined to the cage, thus reducing the amount of unsymmetrical ethane formed. If the assumption is made that, in the liquid phase, once a radical has escaped from the cage its combination reactions are governed by statistical factors alone, then an estimate of the proportion of the radicals escaping from the cage may be made. Thus if the number of radicals involved in the formation of the unsymmetrical ethane $[R_1R_2]'$ (1 : 1 : 2 trichlorotrifluoroethane) outside the cage is calculated from the equation :

$$[R_1R_2]' = 2.([R_1R_1][R_2R_2])^{1/2}$$

and this is added to the number required to produce the two symmetrical ethanes R_1R_1 and R_2R_2 and the methanes R_1Cl and R_2Cl, this sum is the total number of radicals reacting outside the cage. The number reacting inside the cage is given by the difference between the number required to produce the total 1 : 1 : 3 trichlorotrifluoroethane and those required to produce the amount formed outside the cage. That is :

$$[R_1R_2]-[R_1R_2]' \text{ or } [R_1R_2]-2([R_1R_1][R_2R_2])^{1/2}$$

Thus the percentage of radicals escaping from the cage is given by :

$$\frac{[R_1Cl] + 2[R_1R_1] + 2([R_1R_1][R_2R_2])^{1/2}}{[R_1Cl] + 2[R_1R_1] + [R_1R_2]} \times 100$$

and

$$\frac{[R_2Cl] + 2[R_2R_2] + 2([R_1R_1][R_2R_2])^{1/2}}{[R_2Cl] + 2[R_2R_2] + [R_1R_2]} \times 100$$

The values quoted below are in good agreement with theoretical expectations and show that for two similar radicals the combination of which is not diffusion-controlled a direct measure of the efficiency of a solvent cage may be made.

Solvent	Percentage R_1 escaping	Percentage R_2 escaping
1 : 1 : 3 Trichlorotrifluoroacetone	91	89
Perfluoro*cyclo*hexane	89	85
1 . 1 : 3 : 3 Tetrachlorodifluoroacetone	68	76

A complete account of the kinetics of the photolysis of these three ketones is published elsewhere.

Photochemical Formation and Stability of the CF_2 Radical

Ten years ago, Barrow and co-workers observed the ultra-violet absorption bands due to the CF_2 radical, produced during an electrical discharge through fluorocarbon vapour, and commented on its probable stability[1]. Using high-intensity flash photolysis techniques, we have been able to photograph the transient formation and slow decay of the same absorption bands produced from some halogenated ketones. Under our experimental conditions, the strongest absorption bands can be detected as long as 20 msec. after the photolysis flash, confirming the great stability of CF_2 as compared with its analogue CH_2 (ref. 2).

The ketones, which included sym-tetrafluorodichloro-acetone, and 1 : 1 : 3-trichloro-trifluoro-acetone, were photolysed in the vapour phase with the full radiation from a silica discharge lamp; the addition of excess nitrogen ensured the maintenance of isothermal conditions. The manner in which CF_2 radicals could arise in these systems is intriguing, since CF_2 formation would not have been anticipated by analogy with hydrogenated ketones. Certainly, the primary process:

$$R_1COR_2 + h\nu \rightarrow R_1 + CO + R_2$$

occurs, since all the possible ethanes were detected by vapour phase chromatography and mass-spectrometric analysis of the reaction mixture following flash photolysis. However, the simultaneous occurrence of alternative primary steps, of the type:

$$CF_2ClCOCF_2Cl + h\nu \rightarrow CF_2ClCOCF_2\cdot + Cl\cdot$$

yielding substituted acetonyl radicals, has been verified by introducing oxygen as the coolant gas; with each ketone the well-known absorption bands of $ClO\cdot$ were detected immediately following the flash, confirming the primary production of $Cl\cdot$ atoms. (The formation of $ClO\cdot$ via substituted methyl radicals may be discounted, since it has been observed that the flash photolysis of brominated chloromethanes in the presence of oxygen gives rise to $BrO\cdot$, but not $ClO\cdot$, radicals[3].) It may be anticipated that the acetonyl radicals would be unstable, dissociating as:

$$CF_2ClCOCF_2\cdot \rightarrow CF_2Cl\cdot + CO + CF_2$$

thus accounting for the production of CF_2. In this respect, it is significant that no di-acetonyl has been detected among the reaction products. Furthermore, in view of the evident stability of CF_2 it is not unreasonable to suppose that the perfluoroketone molecule would rapidly dissociate.

Preliminary measurements on the decay of the CF_2 absorption suggest that it is zero order, supporting Barrow's suggestion that CF_2 radicals are removed by diffusion to the walls of the reaction vessel[1]. The gradual appearance of a permanent continuous background absorption after several flashes points to the accumulation of a polymeric layer of $(CF_2)_n$ on the reaction vessel windows. No tetra-fluoro-ethylene or volatile CF_2-telomers could be detected among the reaction products, and it would appear that CF_2 is extremely unreactive (compare the marked unreactivity of NF_2 as compared with NH_2).

A fuller account of this and related work in progress will be published at a later date.

We wish to thank Dr. J. R. Majer for the vapour phase chromatography and mass-spectrometric analyses, and Prof. J. C. Robb for his interest in, and encouragement of, this work. A. J. Y. thanks the Department of Scientific and Industrial Research for a maintenance award, and J. P. S. thanks the University of Birmingham for the award of an Imperial Chemical Industries fellowship.

Dependence on Temperature of the Electrical Resistivity of Thermosetting Polymers

To-day's great usage of thermosetting polymers has served to emphasize the lack of fundamental data on the electrical and physical properties of these materials. With the exception of the data published by us[1,2], there is almost none available on the dependence on temperature of the electrical volume resistivity and on the activation energy for the electrical conduction process, E_c, in cross-linked polymers. Data of this type are of great importance not only in technological applications but also in the study of the physics and chemistry of these polymers. For example, it has recently been shown[1,2] that the dependence on temperature of the resistivity is a convenient index of the extent of polymerization. Also, recent work has shown that electrical resistivity measurements can be successfully employed in the study of the reactions and the determination of the extent of polymerization of composite solid propellants[3]. These experimental techniques can likewise be used to investigate the properties of organic semiconductors. It is the purpose of this communication to indicate briefly how these measurements can be accurately and rapidly made and to present typical results.

A continuous current monitoring device[4] is used to determine the dependence on temperature of the resistivity of the polymer. This instrument consists of a Keithley model 210 electrometer, a Keithley model 2008 decade shunt and a cell. The cell consists of two brass parallel plate electrodes separated by two small polytetrafluoroethylene spacers. With this instrumentation it is possible to monitor continuously the large change in resistivity (10^{6}–10^{16} ohm.-cm.) which may occur on heating a polymer. To assure optimum electrical contact, the liquid

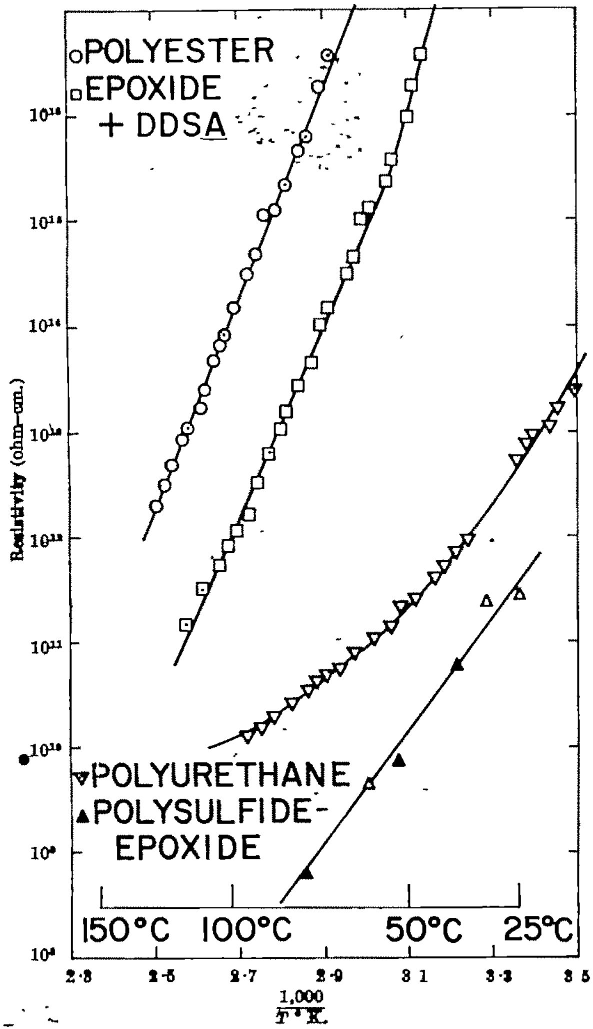

Fig. 1

polymer is polymerized directly to the electrodes which are encapsulated by the polymer. The dependence on temperature of the resistivity of the completely polymerized sample is determined by monitoring the resistivity and the temperature of the sample as it is heated at a rate of about 15° C. per hr. Measurements are made at a field-strength of about 200 V. per cm.

Polymers considered in this communication are typical of the thermosetting types in use. The epoxide was 'Epon 828' (Shell Chemical Co.), a reaction product of 2 moles of epichlorohydrin and 1 mole of *bis*(4-hydroxyphenyl) dimethylmethane[5], and had an epoxide value of 0·54 per 100 gm. It was polymerized with 59·5 per cent of dodecenyl succinic anhydride. The polyester was 'Paraplex *P*-43' (Rohm and Haas Co.), which is reported to consist of 30 per cent styrene and 70 per cent of a linear condensation polymer of maleic and phthalic acids with propylene glycol. This was polymerized using 1 per cent methyl ethyl ketone peroxide as a catalyst. The polysulphide-epoxide copolymer was a 50 : 50 mixture of a mercaptan terminated saturated elastomer and 'Epon 828'. The polysulphide was a reaction product of *bis*(2-chloroethyl) formal and sodium polysulphide[6]. Diethylaminopropylamine at a concentration of 3 per cent was used as a hardener. The polyurethane was a reaction product of a polyester glycol and 2,4-tolylene di*iso*cyanate which is cross-linked with 40 per cent castor oil.

It will be noted in Fig. 1 that in three of the polymers considered, the electrical volume resistivity, ρ, changes with the absolute temperature, *T*, in accordance with the general relationship:

$$\rho = \rho_0 \exp[E_c/RT]$$

where ρ_0 is a temperature-independent constant, *R* is the gas constant in cal./deg. mole, and E_c is the activation energy for the electrical conduction process. This activation energy was found to be 70 kcal./mole for the epoxide + dodecenyl succinic anhydride at temperatures below 54° C. and 43 kcal./mole above this temperature. The change in the slope of the resistivity versus temperature plot at 54° C. can be attributed to a glass transition within the polymer[3]. For the polyester polymer, E_c was 46 kcal./mole and for the polysulphide-epoxide copolymer 24 kcal./mole. A nonlinear temperature dependence of the resistivity is exhibited by the polyurethane which may be due to the internal plasticization of this polymer, probably by the excess castor oil.

All the resistivity versus temperature plots shown in Fig. 1 have the maximum slopes that can be obtained for these polymers. These plots, therefore, represent the greatest extent of polymerization possible.

It has been previously shown[1,2] that during polymerization the dependence on temperature of the resistivity increases as a function of the extent of polymerization. Thus, the dependence on temperature, or more conveniently E_c, is an index of the extent of polymerization. Prolonged heating at high temperatures or pyrolysis of these polymers will result in degradation, which is evidenced by a decrease in the slope of the resistivity versus temperature plot. It has been observed that thermosetting polymers generally exhibit a greater dependence on temperature and magnitude of the resistivity at 25° C. than linear polymers. The polysulphide-epoxide copolymer is an exception to this generalization.

Work is continuing in an effort to develop additional data and to broaden the use of the continuous current monitoring device to relate fundamental electrical properties to the structure and physical properties of thermosetting polymers. Additional data on thermosetting polymers, the experimental technique, and a discussion of the nature of the electrical conduction process in polymers will be published at a later date.

'Enthalpy Titrations' and Thermochemistry in Molten Salts

AUTOMATIC instrumentation for recording 'thermometric titration' curves has been described in recent papers[1,2] from these laboratories, which represent the first report of a continuous titration procedure successfully carried out in a molten salt solvent. This approach is capable of yielding a wealth of quantitative information on the chemistry of fused salts. Significant thermochemical results, involving the precipitation of silver halides and of silver chromate, are summarized in this communication. A typical titration curve (of chromate with silver), obtained under essentially adiabatic conditions, is illustrated in Fig. 1. Methodologically this is a differential thermometric titration curve, because temperature has been recorded as a function of the amount of titrant. From a phenomenological point of view, however, Fig. 1 represents an 'enthalpy titration', the shape of the curve reflecting the heat evolved in the reaction as a function of added silver.

The following types of data can be inferred from a judicious interpretation of the titration curves: (*a*) The stoichiometry of the reaction occurring in the fused solvent, if concentrations of the reactants are known (the abscissa projection $B'C'$ represents a measure of the mole ratio of titrant to 'titrate' (Fig. 1) at the extrapolated end-point C). (*b*) The amount of reactant in a titrate of unknown concentration, provided the stoichiometry is known, and a standard solution of titrant is used. (*c*) The heat of the titration reaction, $\Delta H°$, calculated from the extrapolated change in temperature BB'. (*d*) The solubility product, K_{sp}, and the corresponding free energy of precipitation, $\Delta F° = RT \ln K_{sp}$, computed from the curvature in the vicinity of the end-point. (*e*) The entropy of the reaction, $\Delta S° = \dfrac{\Delta H° - \Delta F°}{T}$. Ideal thermodynamic parameters were obtained, because effective reactant concentrations in the titration cell were maintained in a range between 10^{-4} and 10^{-2} molal, where heats of dilution were found to be negligible. The change in temperature, BB', in a titration was of the order of 0·01–0·5° C., at mean temperatures of 500–800° K. The corresponding variability of the thermodynamic functions is negligible, yielding virtually isothermal enthalpies, free energies, and entropies, corresponding to the 'median temperature' of the titration curve, T (Fig. 1). The change in temperature during the titration was monitored in the titrated melt by means of a thermistor bridge having a sensitivity threshold of 0·0003° C. Random temperature fluctuations were minimized to ±0·0005° C. with the aid of a special adiabatic titration cell in a supernatant argon atmosphere. The titrant was delivered by remote control, via a motor-driven syringe-burette. Titrant and titrate were dissolved in identical fused salt solvents[2].

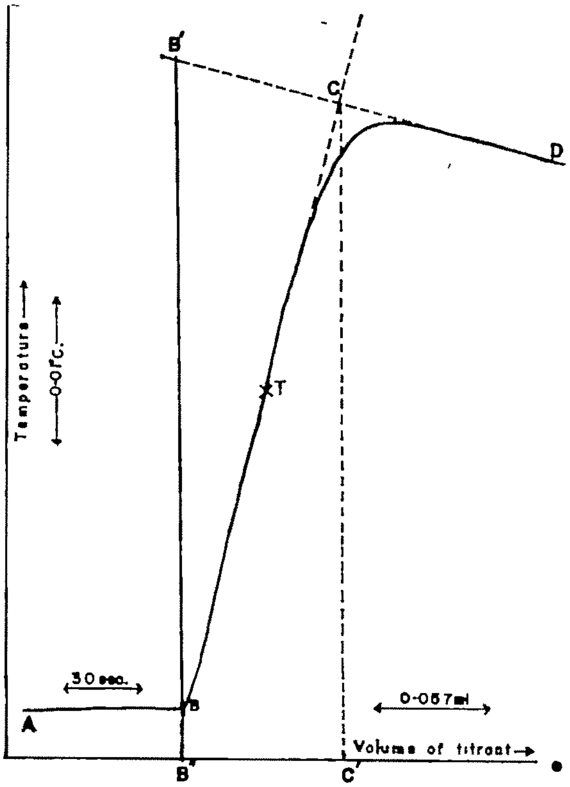

Fig. 1. Thermometric titration of 5·556 × 10^{-2} m. K_2CrO_4 titrate with 12·78 m. $AgNO_3$ titrant in fused $LiNO_3$—KNO_3 at 431° K. Amount of titrate melt, 99·3 gm. *AB*, Temperature–time blank, prior to start of titration; *B*, start of titration; *C*, end-point, $2Ag^+/1CrO_4^{--}$; *CD*, excess reagent line; *T*, median temperature

A representative set of results is shown in Table 1. As is evident from column 3, thermometric titrations are applicable to quantitative volumetric analysis with a precision and accuracy of the order of 2 per cent, at concentration-levels as low as 10^{-3} molal. Extensive applications are anticipated to the determination of halides and silver, *in situ* in molten salts at elevated temperatures. Of the thermodynamic parameters, the entropies offer interesting possibilities for direct qualitative interpretation as a measure of order–disorder situations. For example, the fact that the precipitation of silver chromate at 431° K. was virtually anentropic in a fused alkali nitrate solvent suggests that chromate existed in the melt as an associated 'polychromate' species. In contra-

RADIATION CHEMISTRY

Chemical Effects of Ionizing Radiations on Nucleic Acids and Nucleoproteins

RECENT work[1] on the effects of ionizing radiations on nucleic acids (deoxyribonucleic and ribonucleic acids) in aqueous systems has shown quite clearly that the reactive species produced from the water attack mainly the constituent purine and pyrimidine bases and, to a lesser extent, the sugar moieties of these polynucleotide molecules. The extents of destruction of the individual bases on irradiation of deoxyribonucleic solutions (0·005 per cent) in the presence of oxygen (1 atm.) were measured and found to be as follows (G = molecules/100 eV.): $G(-\Delta\text{thymine}) = 0{\cdot}33$; $G(-\Delta\text{adenine}) = 0{\cdot}25$; $G(-\Delta\text{cytosine}) = 0{\cdot}23$; $G(-\Delta\text{guanine}) = 0{\cdot}18$. Breakage of the strands in the deoxyribonucleic acid helix is apparently mainly due to an attack of the radicals produced by irradiation on the sugar moieties, which leads to a splitting of the phosphate ester linkages along the chains. The extent of attack which leads to breakage of internucleotide bonds, leading to the production of phosphomonoester groups, has been determined directly with monophosphoesterase; the number of end-groups formed on irradiation with 200 kV. X-rays gives a yield of $G \simeq 0{\cdot}5$. Rupture of hydrogen bonds within the helix is a consequence of chemical changes in the polynucleotide chains; several hydrogen bonds can be broken following a single chemical event.

The hyperchromic effect which is observed in the action of the radiations on nucleic acids in solutions has been investigated in some detail. It has been concluded that this effect is caused, in general, by environmental changes of the chromophoric groups of the purine and pyrimidine bases of deoxyribonucleic acid, and is due to the change from the hydrogen bonding of the bases within the intact helix (where the bases of one strand are bonded to the bases of the complementary strand), to hydrogen bonding with water molecules when the latter have penetrated between the strands of the helix.

The chemical nature of the reactions induced by irradiation of nucleic acid has been studied in some detail by investigating solutions of the purine and pyrimidine bases and of the corresponding nucleosides and nucleotides[1].

Since deoxyribonucleic acid is generally found in biological systems in the form of nucleohistones or nucleoprotamines, a point of particular interest appeared to be a study of the changes induced by irradiation in deoxyribonucleic acid when combined with protein in the nucleoproteins.

Aqueous solutions of calf thymus nucleoprotein were prepared from fresh calf thymus glands by Doty and Zubay's method[2] using a Dounce homogenizer. Solutions (~ 0·02 per cent) were saturated with oxygen (1 atm.) for 15 min. prior to irradiation. The deoxyribonucleic acid used was kindly supplied by Prof. J. A. V. Butler. Calf thymus histone was obtained from the Mann Research Laboratories.

The irradiations were carried out with X-rays from a Victor 'Maximar' therapy tube operating at 200 kV. and 15 m.amp. Solutions were irradiated in 'Pyrex' glass vessels of the type previously described[3]. The dose-rate as determined by the Fricke dosimeter was 2,900 rads/min.

Experiments were carried out in which the total individual base compositions of irradiated and unirradiated nucleoprotein solutions were determined. For this purpose, samples were hydrolysed with formic acid and this was followed by chromatographic separation, using a butanol–ammonia system[4], and spectrophotometric estimation of the individual purines and pyrimidines. The results show quite clearly that up to doses of about $1{\cdot}3 \times 10^5$ rads, the bases of the nucleic acid were not detectably attacked by the radiation.

Another way of detecting any chemical modifications of the nucleic acid component involves determination of the rate of release of inorganic phosphate on hydrolysis at elevated temperatures[5]; this is rather a sensitive method, and has been successfully employed in irradiations of solutions of deoxyribonucleic acid. Solutions of nucleoprotein were irradiated, treated with catalase (to decompose hydrogen peroxide) and with chymotrypsin (to degrade protein) and then hydrolysed at 90° at pH 7·5. The rate of release of inorganic phosphate was almost exactly the same in the irradiated as in the unirradiated blank solutions. This latter result would therefore confirm that in the intact nucleoprotein no detectable attack on the polynucleotide takes place.

In contrast to these findings, it was found that on irradiation of solutions of synthetic mixtures of calf thymus deoxyribonucleic acid and histone, there was some degradation of the deoxyribonucleic acid component, but much less than in pure deoxyribonucleic acid solutions. In the synthetic mixtures, the protein protected the deoxyribonucleic acid to some extent, as would be expected from the fact that the free radicals produced by irradiation can distribute themselves between the nucleic acid and the protein.

We must conclude, therefore, that in the intact nucleoprotein as isolated from calf thymus glands, the active species produced by irradiation are unable to penetrate the protein sheath; apparently, up to doses as high as 10^5 rads practically all of them react with the protein and the deoxyribonucleic acid remains substantially undamaged. This chemical evidence is in agreement with the observation of Kaufmann *et al.*[6] that irradiation of nucleoprotein did not appreciably alter the viscosity of the deoxyribonucleic acid component.

These findings may explain the high radiosensitivity of the nucleus during certain stages of the mitotic cycle, when the protein is shed from the deoxyribonucleic acid.

We thank the Rockefeller Foundation and the Northern Council of the British Empire Council Campaign for financial support. One of us (P. E.) also thanks the Department of Scientific and Industrial Research for a maintenance grant. One of us (J. W.) would like to thank Prof. G. de Hevesy for interesting discussions.

BIOPHYSICS

Electrostatic Measurement of the Geoelectric Effect in Coleoptiles

The so-called geoelectric potential, which develops between the upper and lower side of a plant when it is placed in a horizontal position, has been investigated by many workers[1–5] using different types of fluid electrodes which were applied directly to both sides of the plant. The original explanation of the cause of this potential given by Brauner[6] has lately proved to be unsatisfactory[7] and a new theory was proposed[8]. To test this theory it was necessary to carry out electric measurements on plants during much longer periods of time than has been done earlier. This was possible by using electrodes somewhat similar to those devised by Clark[9]. The results obtained by this method were difficult to reproduce and differed generally from those reported by earlier workers. During extensive measurements on *Avena* coleoptiles, *Pisum*, *Helianthus* and *Zea mays*, it was found that the results are often strongly influenced by the direct-contact electrodes. Therefore, it was thought necessary to measure these potentials without touching the plants at all, and to this end an entirely new measuring technique was developed.

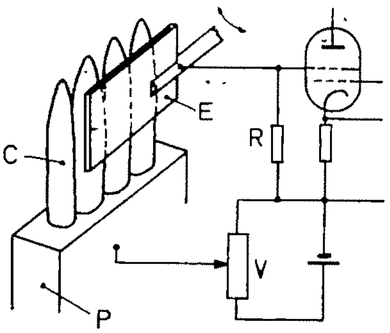

Fig. 1. Measurement of the geoelectric potential by means of the vibrating reed principle. This method permits the potential measurement with the vibrating electrode *E* without touching the coleoptiles *C*

This method makes use of the vibrating reed principle[9]. A thin plane gold electrode, 5 mm. × 10 mm., is placed at a distance of about 1 mm. from three to seven *Avena* or *Zea mays* coleoptiles placed in a row (see Fig. 1). This electrode is carefully insulated and is vibrated at a frequency of about 250 c./s.; it is earthed through a resistance *R* of 10^{10} ohms. If an electric field exists between the coleoptiles and the vibrating electrode, an alternating voltage will be generated across the resistance *R*. This voltage signal is applied to the grid of an electrometer tube connected as a cathode follower, and after further selective frequency amplification displayed on a cathode-ray tube screen. The other plate of the vibrating condenser is formed by the coleoptiles themselves. They are usually cut about 15 mm. from the apex and inserted into a 'Plexiglas' container *P* filled with tap water. With a miniature calomel electrode[10] in contact with this water reservoir, the potential of the coleoptiles can be varied at will by a variable voltage *V* (Fig. 1).

The a.c. signal generated by the vibrating electrode *E*, which is displayed on the cathode-ray tube, is roughly proportional to the magnitude of the electric field between the coleoptiles *C* and the electrode *E*. Therefore, by adjusting the voltage *V* properly, the a.c. signal can be reduced to zero, thus indicating that the field-strength and the potential between the coleoptiles *C* and the electrode *E* is zero.

If, after this adjustment, the apparatus is placed in a horizontal position and a geoelectric potential appears on the surface of the coleoptiles, an a.c. signal is generated again because of the electric field due to this potential. By varying the voltage *V*, this signal can be reduced to zero again, the variation of *V* being roughly equal to the potential developed by the coleoptiles. Measuring this potential with the electrode *E* above and below the plants and applying a correction factor for the geometry of the coleoptiles, the true geoelectric potential can be found.

The results of such measurements, the reproducibility of which is definitely superior to the conven-

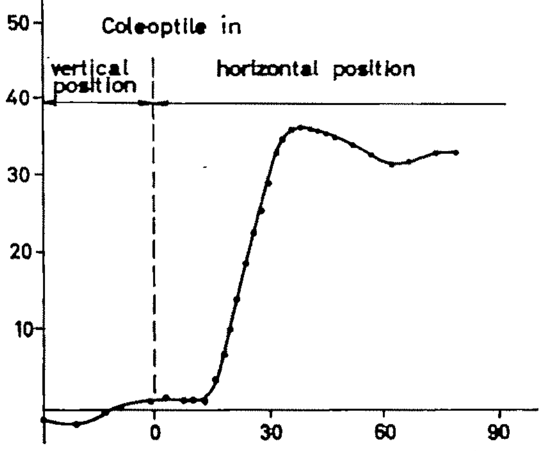

Fig. 2. Geoelectric potential generated across etiolated *Avena* coleoptiles when placed in a horizontal position, as measured by the vibrating reed method

tional method, are shown in Fig. 2. The measurements have been made on etiolated *Avena* and *Zea mays* coleoptiles in the dark. Contrary to previous results, the geoelectric voltage does not appear until 15 min. after tilting the plants into a horizontal position. This has been corroborated with *Avena*, *Pisum* and *Zea mays* by our extensive experiments with the conventional method using electrodes similar to the Clark type[5]. Further, the magnitude of the voltage is greater than that reported by the majority of previous authors. A more detailed description of the method and results with different plant materials will be published elsewhere.

I thank Prof. H. Burström, of the Botanical Laboratory, Lund, for his encouragement and advice.

BIOCHEMISTRY

Screw Sense of the α-Helix in Poly-β-benzyl-L-aspartate

Blout and Karlson[1] have reported that the constant b_0 in Moffitt's equation for the dispersion of optical rotation[2] has values up to + 630° for solutions of poly-β-benzyl-L-aspartate in chloroform; the usual value for solutions containing α-helices of polypeptides is about − 600°, and corresponds to right-handed helices[3]. We have studied the dispersion of a number of copolymers of β-benzyl-L-aspartate with other amino-acids, and believe that the results demonstrate that the positive b_0 found for poly-β-benzyl-L-aspartate is due to a left-handed helix and not to an optical anomaly.

If we plot b_0 against composition for a series of random copolymers of β-benzyl-L-aspartate and γ-benzyl-L-glutamate, we find that although the values of b_0 for the two simple polymers are almost equal (though of opposite sign) the curve is very far from symmetrical. Eight mole per cent of L-glutamate is sufficient to reduce b_0 to zero[4], and more than 85 per cent of the total change in b_0 is produced by the addition of 15 mole per cent of L-glutamate; the effect of L-alanine residues is similar. These results are best explained by the hypothesis that the two simple polymers form α-helices of opposite screw senses, and that the preference of the L-aspartate residues for a left-hand helix is much less marked than that of the L-glutamate residues for a right-hand helix, so that comparatively few of the latter can dictate the sense. To explain these results on the basis of an optical anomaly we would have to postulate that this anomaly depends on long unbroken sequences of L-aspartate residues. However, other experiments show that the sequences of L-aspartate residues may be interrupted by either D-glutamate or D-aspartate residues with very little effect on b_0.

These conclusions are confirmed by measurements on a number of other copolymers, both random and block, and by building molecular models. A full account of this work will be published elsewhere.

Isolation and Probable Functions of Betaine Esters in Brain Metabolism

IN previous work, Hosein[1] reported that γ-butyrobetaine was found in extracts made from brain tissue of rats in convulsions which had been induced by intraperitoneal injections of cerebral convulsants. We have now found that fractionation of the gold precipitate formed from eluates of the chromatograms made from these extracts by the procedure of Linneweh[2] enables the identification of two other betaines. The melting points of the gold derivatives of the betaines obtained in this investigation are shown in Table 1 and compared with those obtained by Linneweh for synthetic betaines.

Table 1. MELTING POINTS OF GOLD DERIVATIVES OF VARIOUS BETAINES

Substance	Melting point (with decomposition) in deg. C Linneweh	 Betaine isolated
γ-Butyrobetaine	180–184	177–181
Crotonbetaine	212–214	209–211
Carnitine	150–153	149–153

From these results we conclude that the brain extracts from animals treated with cerebral convulsants contained free γ-butyrobetaine, crotonbetaine and carnitine.

Other work by Hosein[3] has shown that in normal brain extracts these betaines in the free form could not be detected. It was shown that the 'free' or immediately extractable acetylcholine from aqueous brain extracts (supernatant *A*) contained acetylcholine and propionylcholine, while the 'bound' fraction, released after chloroform treatment (supernatant *B*), contained, in addition to these choline esters, a mixture of the coenzyme A ester derivatives of the betaines mentioned above. These betaine esters were contained in a band of the chromatogram developed in the butanol/water system with an R_F between 0·45 and 0·56. The chromatogram pattern obtained from the 'bound' acetylcholine fraction in brain was similar to that obtained by Bannister *et al.*[4], who used ox spleen. We have synthesized enzymatically γ-butyrobetaine–coenzyme *A*, and this substance has an R_F of 0·55 in the butanol/water system. This thiol ester was found to possess acetylcholine-like properties similar to those obtained with eluates of the 0·45–0·56 band obtained from brain extracts. In both cases their physiological effects are abolished by atropine. Accordingly, it appeared from these results that both the 'free' and 'bound' extractable acetylcholine from brain is not solely due to acetylcholine alone. The presence of the betaine-coenzyme *A* esters exclusively in the 'bound' acetylcholine fraction may accordingly be of significance in brain metabolism.

Other experiments by our group[3,6] and by others[7,8] have shown that ester derivatives of these betaines have acetylcholine-like properties, whereas the free (unesterified) betaines are inactive. Previously, Hosein and McLennan[5] described some pharmacological properties of the methyl ester of γ-butyrobetaine. In that paper γ-butyrobetaine was described as having these acetylcholine-like properties, but actually the methyl ester was used; this material was erroneously supplied to us as γ-butyrobetaine and accordingly it was used as such. We[1] have found that the methyl, ethyl and choline esters of γ-butyrobetaine are extremely powerful convulsants. Accordingly, it seemed possible that, *in vivo*, betaine esters could also be concerned with convulsive activity in brain, while the presence of the free betaines mentioned above could have been due to ester hydrolysis either *in vivo* or during the extraction process.

We have repeated our previous experiments, in which cerebral and spinal convulsants were injected intraperitoneally into rats, to determine whether betaine esters could be detected in the supernatant *A* fraction of the brain suspensions of these treated animals. The convulsants used were dieldrin, ammonium chloride, metrazol, picrotoxin, camphor and strychnine. In comparison experiments, cerebral convulsions were produced by electroshock. As before, all animals were killed during the convulsions and untreated animals served as controls. Examination of the chromatogram shown in Fig. 1 shows that, in addition to acetylcholine and propionylcholine normally present in supernatant *A*, when brain extracts made from animals treated with electro-shock or when cerebral convulsants were used, there was a band at R_F 0·45–0·56, which contained the betaine coenzyme *A* esters. This was not observed when strychnine was used. In normal animals this band was only found in supernatant *B*, that is, the tissue residue which had been treated with chloroform[3]. The presence of the betaine esters in the supernatant *A* fraction suggests that they were released from their normal cellular attachments by some action of the convulsive agents, and since they have been found to be indistinguishable from acetylcholine on assay preparations, they may be concerned with the initiation of the convulsions.

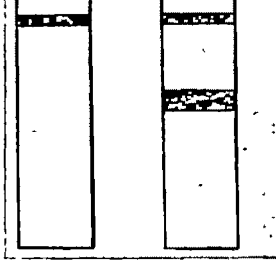

Fig. 1

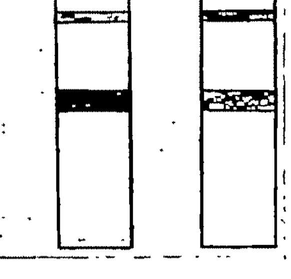

Fig. 2

Fig. 1. Release of betaine esters (R_F 0 45–0 56) in brain tissue during convulsions

Fig. 2. Distribution of betaine esters in the cerebellum and the cerebral cortex of normal rats

There are many indications that there may be several substances in brain other than acetylcholine which could have transmitter properties. The low choline acetylase activity and concentration of acetylcholine in the cerebellum are indicative of this[9,10]. Results of paper chromatographic analysis of chloroform-treated extracts, supernatant *B*, of the cerebellum and of the cerebral cortex of normal rats (see Fig. 2), have shown that the cerebellum contains a higher concentration of these betaine coenzyme *A* esters than does the cerebral cortex. This suggests that these betaine coenzyme *A* derivatives may function as transmitter substances in the cerebellum and perhaps also in other regions of the brain. An evaluation of the physiological properties of the coenzyme *A* ester derivatives of γ-butyrobetaine, crotonbetaine and carnitine is now in progress.

Effect of Potassium Cyanide Poisoning on the γ-Aminobutyric Acid-Level in the Brain

SEVERAL substances, which affect brain metabolism, act upon the γ-aminobutyric acid-level in that organ[1]. Insulin-induced hypoglycæmia brings about a drop in the γ-aminobutyric acid-level, probably as a result of decreased glutamic acid concentration. The administration of some substances, known to inhibit glutamic acid decarboxylase, leads also to a drop in the level of γ-aminobutyric acid in the brain. Thus, semicarbazide, an inhibitor combining with the aldehyde group of pyridoxalphosphate, reduces the γ-aminobutyric acid-level in the brain by approximately 30 per cent[2]; in a similar way, 2-methyl-4-amino-5-oxymethylpyrimidine brings about a drop[3]. After the ethanol ingestion, however, the level of γ-aminobutyric acid content in the brain was found to be increased[4].

Potassium cyanide is a substance which inhibits the activity of glutamic acid decarboxylase, as has been shown by *in vitro* experiments by Wingo and Awapara[5]. This inspired me to follow the effect of cyanide poisoning on γ-aminobutyric acid in the brain.

Experiments were carried out on albino rats of Wistar *B* strain weighing 200–300 gm. Cyanide was administered intraperitoneally in the doses of 40 and

10 mgm./kgm. in 0·5 ml. After the stage of convulsions (1–4 min. following administration of potassium cyanide), the animals were decapitated. After weighing, the brain was homogenized in a homogenizer according to Potter and Elvehjem in 1 per cent picric acid solution. The homogenate was centrifuged, and the picric acid removed on a 'Zerolith *FF*' column. The brain extract thus treated was placed on chromatography paper Whatman 1 and submitted to electrophoretic partition in pyridin–acetate buffer at 26 V./cm. Electrophoretic partition and quantitative determinations of γ-aminobutyric acid and glutamic acid were made according to Wingo and Awapara[5], with the only difference that 0·5 per cent ninhydrin solution was prepared in aqueous acetone (90 ml. acetone + 10 ml. water), saturated with sodium carbonate. Optical density was measured on Zeiss spectrophotometer at 570 mμ.

Table 1

	No. of determ-mations	γ-Amino-butyric acid (μgm./gm. of wet weight)	*P*	Per cent
Control animals	25	303 (417–236)		100
Animals poisoned with potassium cyanide—40 mgm./kgm.	25	244 (330–186)	<0·01	80·5
Animals poisoned with potassium cyanide—10 mgm./kgm.	13	252 (341–180)	<0·01	83·0

As shown in Table 1, potassium cyanide poisoning causes a decrease of γ-aminobutyric acid by 19·5 or 17 per cent respectively.

When calculated for the dry weight of the brain of the control animals and of those poisoned with potassium cyanide, the concentrations in per cent were the same as given in Table 1.

After the administration of potassium cyanide the blood-level of γ-aminobutyric acid did not rise.

Table 2

	No. of determ-mations	Glutamic acid (μgm./gm. of wet weight)	*P*	Per cent
Control animals	14	1,855 (1,750–2,250)		100
Animals poisoned with 40 mgm. potassium cyanide/kgm.	14	2,130 (1,840–2,560)	<0·02	115
Animals poisoned with 10 mgm. potassium cyanide/kgm.	13	2,040 (1,720–2,620)	<0·05	110·5

Table 2 illustrates the changes of glutamic acid concentration in the brain following poisoning with potassium cyanide.

The decrease of concentration of γ-aminobutyric acid is probably due to inhibition of glutamic acid decarboxylase. This presumption is confirmed by the inhibition of glutamic acid decarboxylase *in vitro*, partly by a rise in glutamic acid concentration. In 1 gm. of wet tissue, there is a rise of 1·5–2·0 μ*M* in glutamic acid concentration. There is a drop of 0·5–0·6 μ*M* of γ-aminobutyric acid concentration, meanwhile.

The activity of the mechanisms of γ-aminobutyric acid degradation *in vitro* (transamination and oxidation) is relatively low. On the other hand, the rate at which changes in γ-aminobutyric acid-levels occur, following poisoning with potassium cyanide, indicates that this compound is intensely metabolized in the brain tissue *in vitro*.

A New Method for the Differential Precipitation of Nucleic Acids from Aqueous Solutions

Many metallic ions are capable of reacting with sodium nucleates in aqueous solutions[1,2]. In these investigations, no attempt seems to have been made to differentiate between the reactivity of the two types of nucleic acid.

It has been found that the addition of an aqueous solution of indium chloride ($InCl_3$) to acetate-buffered solutions of highly polymerized nucleic acids in the presence of sodium chloride results in the formation of a precipitate containing indium and nucleic acid. This reaction, which does not seem to have been previously described, is a function of *p*H and ionic strength. By varying the ionic strength, it was possible to precipitate selectively either deoxyribonucleic acid or ribonucleic acid from aqueous solutions.

The quantitative precipitation of the two acids was carried out in a final volume of 5·0 ml. containing the following:

Deoxyribonucleic acid, prepared according to Kay *et al.* (ref. 3), 0·4 per cent in 0·14 *M* sodium chloride	0·5 ml.
Ribonucleic acid, prepared according to Crestfield *et al.* (ref. 4), 1·0 per cent in 0·14 *M* sodium chloride	0·5 ml.
Acetate buffer, 0·4 *M*, *p*H 5·0	0·5 ml.
Distilled water	3·0 ml.
Indium chloride, purchased from the Indium Corporation of America, Utica, N.Y., 0·05 *M* aqueous (freshly prepared)	0·5 ml.

After thorough mixing of these components, the solution is allowed to stand for 30 min. at room temperature and then centrifuged at 1,400*g* (International Laboratory Centrifuge) for 10 min. The supernatant solution contains only negligible quantities of material absorbing ultra-violet light at 260–280 mμ.

The optimal *p*H for the quantitative precipitation of the nucleic acids in the presence of 0·005 *M* indium chloride was established on the basis of experimental data shown in Fig. 1. In these experiments carried out separately with either deoxyribonucleic acid, ribonucleic acid or protein, the *p*H of the acetate buffer was varied over the range 2·9–5·8. The extent of precipitation of either nucleic acid, and for comparison bovine serum albumin (purchased from the Nutritional Biochemicals Corp., Cleveland, Ohio), was measured by determining the optical density of the supernatant solution at 260 mμ (nucleic acids) or 280 mμ (protein). Results for deoxyribonucleic acid and albumin were reproducible from one preparation to another. Ribonucleic acid was dialysed against 0·14 *M* sodium chloride at 4° C. for 48 hr. and if used immediately gave closely reproducible results. It should be emphasized that more than 95 per cent of

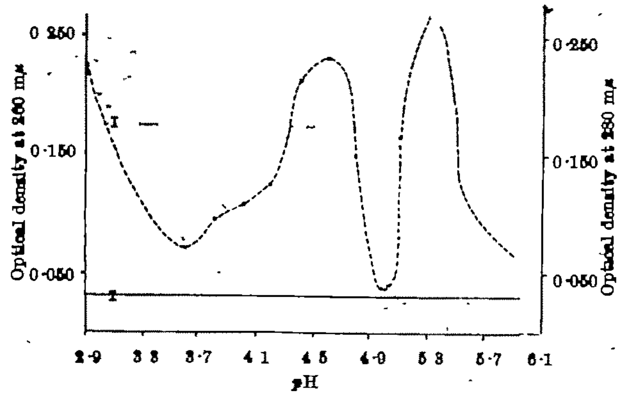

Fig. 1. Amounts of deoxyribonucleic and ribonucleic acids and bovine albumin remaining unprecipitated by indium at various pH levels and expressed as optical densities of the supernatant solutions as described in the text. Ribonucleic acid was dialysed against 0·14 *M* sodium chloride and used immediately after dialysis. ——, Deoxyribonucleic acid; – – – –, ribonucleic acid; . . . . , albumin

the ribonucleic acid in solution has been precipitated even at pH 5·3.

It was found that, by increasing the sodium chloride concentration to 4 *M* (other conditions remaining as described above), deoxyribonucleic acid remained in solution whereas ribonucleic acid under the same conditions was precipitated. Thus, after precipitation of ribonucleic acid at a final concentration of sodium chloride of 4 *M*, deoxyribonucleic acid remains in solution and, in turn, can be isolated by dialysis against buffered 0·14 *M* sodium chloride followed by addition of indium chloride to the dialysed solution. The two nucleic acids can be separated from a mixture quantitatively by this procedure.

This investigation, which was supported in part by a grant from the U.S. Atomic Energy Committee, will be reported elsewhere in detail, together with data on the isolation of pure nucleic acids from tissues.

5-Hydroxytryptamine in Cerebrospinal Fluid

ALTHOUGH the 5-hydroxytryptamine content of human cerebrospinal fluid has been reported by Sachs[1] to increase after various head injuries or cerebral tumours, there appears to be no other reference in the literature to conditions resulting in an alteration in the content. While studying tuberculous meningitis in children, the opportunity arose for the cerebrospinal fluid to be tested for various amines including 5-hydroxytryptamine.

The cerebrospinal fluid was withdrawn from the patients using conventional methods, taking special care not to contaminate the samples with blood. The fluid was then tested either directly or after acetone extraction on the rat fundus preparation according to the method of Vane[2]. In 20 cases of tuberculous meningitis, the range of 5-hydroxytryptamine values was 0·2–3·0 μgm./ml., whereas in control children it was 0·03–0·1 μgm./ml. The more severe cases always showed high 5-hydroxytryptamine activity. Further, the clinical course of the disease closely followed the 5-hydroxytryptamine content of the cerebrospinal fluid. The significance of these findings is not yet clear.

Viscosity of Concentrated Urea–Lithium Bromide Solutions

IN the course of studies involving the physicochemical characterization of a proteolytic enzyme from a strain of *B. subtilis* (*NOVO* enzyme), viscosity measurements of the protein in concentrated urea and lithium bromide solutions were undertaken. For these studies, a 1 per cent solution of the protein was employed, and outflow times were measured at 20·0° in a modified Ostwald viscometer.

The results obtained in simple aqueous solution, 8 *M* urea and 7 *M* lithium bromide, are presented in Table 1. The significance of these results, in so far as characterization of the specific protein is concerned, will be discussed elsewhere (Geschwind and Ottesen, to be published). Of interest here are the outflow times found for the solvent, which is both 8 *M* with respect to urea and 7 *M* with respect to lithium bromide. Even in the absence of protein the outflow time for this solution is very great, as is shown in Table 1; the actual increment in outflow time above that found for water is approximately nine times greater than the sum of the individual increments for 8 *M* urea and 7 *M* lithium bromide. The outflow time is strikingly dependent upon the concentration of the two solutes, for as shown in the last line of Table 1, dilution of the solution by a factor of less than 8 per cent diminishes the outflow time by more than one-third. At the higher concentrations of urea and lithium bromide, the addition of protein to 1 per cent further increases the outflow time by approximately 150 sec.

Table 1

Solvent	Protein present	Outflow time (sec.)
Water	–	67·4
	+	69·0
8 *M* urea	–	99·2
	+	102·5
7 *M* lithium bromide	–	111·0
	+	122·5
8 *M* urea + 7 *M* lithium bromide	–	726
	+	874
7·4 *M* urea + 6·5 *M* lithium bromide	–	469

These results indicate that when both urea and lithium bromide are present in high concentrations in a solution marked interactions occur, and further, that the contribution of the protein in increasing the outflow time may be envisaged as arising from its effect on the solvent, rather than from an effect of the solvent on the protein. One type of interaction that might be involved is the formation of complexes of the general formula $LiBr.nCO(NH_2)_2$ (ref. 1). Another type of interaction is suggested by the claim that in strong urea solutions chain-like molecules form and collect together to give fibrils[2]. Such chains would arise from linear hydrogen-bonding, and the fibrils from lateral dipole–dipole interactions. On the basis of further experimental results, it was concluded that such fibrils are readily destroyed by the addition of dilute acetic acid to the strong urea solutions[2]. When the concentrated urea–lithium bromide solution employed here, however, was diluted with 1 *M* acetic acid rather than with water, to give a solution which is 7·4 *M* in urea and 6·5 *M* in lithium bromide (see last line of Table 1), no reduction in outflow time beyond that recorded for the solution diluted with water was observed.

If long fibrils do indeed form in 8 *M* urea solutions, their stability may be decidedly enhanced in the presence of concentrated lithium bromide by a mechanism (depression of the thermodynamic activity of water) similar to that proposed[3] for the stabilization by lithium bromide of hydrogen-bonding in proteins. If such a mechanism were operative, then the marked reduction in outflow time effected by dilution, as reported above, must arise from an inability of the long chains to form as readily in 7·4 *M* urea as in 8 *M* urea, rather than from the small difference in the activity of water in the two solutions.

This work was carried out at the Carlsberg Laboratory during the tenure of a National Science Foundation Senior Post-doctoral Fellowship.

An Inverse Relation between the Liver Glycogen and the Blood Glucose in the Rat adapted to a Fat Diet

THE discovery by Claude Bernard[1] of the role of the liver glycogen in maintaining the blood sugar is well known. The liver was observed by Soskin *et al.*[2] to remove glucose from the blood when there was hyperglycaemia and to add it to the blood during hypoglycaemia. Later, the rate of uptake or output of glucose was shown to be directly proportional to the degree of the hyper- or hypo-glycaemia[3]. Recently an enzymic mass-action mechanism dependent on the effective intracellular concentration of hepatic glucose-6-phosphate has been put forward[4] to explain this regulation (the liver cells being freely permeable to glucose). However, while this mechanism may operate in animals adapted to the metabolism of glucose as the primary fuel, experiments in this laboratory have shown that in the rat adapted to a fat diet, the relationship between the liver glycogen and the blood glucose as outlined above is no longer evident.

Table 1. QUANTITY OF LIVER GLYCOGEN AND LEVEL OF BLOOD GLUCOSE IN RATS STARVED FOR 24 HR. THEN FED ON VARIOUS AMOUNTS OF BUTTER-FAT FOR FIVE DAYS

	Butter-fat fed (gm./day)				Normal fed controls
	2	4	5	6	
Liver glycogen (mgm./100 gm. of initial body-weight)	2·9 ± 0·9 (8)	25·1 ± 7·2 (8)	49·0 ± 6·8 (7)	63·7 ± 10·5 (10)	190·5 ± 11·6 (11)
Blood glucose (mgm./100 ml.)	64·4 ± 6·6 (8)	58·6 ± 4·8 (8)	55·1 ± 6·4 (6)	38·6 ± 4·0 (10)	79·4 ± 1·8 (14)

Values are the mean results ± the *S.E.* The number of animals is shown in parentheses.

Female albino rats (200 gm.), fasted for 24 hr. to reduce the liver glycogen to negligible amounts, were fed with 2, 4, 5 or 6 gm. of butter-fat per day. After five days on this diet, blood was taken from the tail for estimation of glucose[5], the animals were killed, and their liver glycogen content determined. The experimental procedures are described in greater detail in a previous publication[6]. The results (Table 1) show that the liver glycogen content rose proportionately to the quantity of fat fed per day ($P <$ 0·001), confirming previous results[6]. On the other hand, as the daily intake of fat was increased so the blood glucose-level fell ($P =$ 0·001–0·01), establishing an inverse relationship between the liver glycogen content and the blood glucose concentration ($P =$ 0·001–0·01).

When the female rat, weighing 200 gm., is consuming 6 gm. of fat per day, the calorie requirement is satisfied and ketogenesis becomes reduced or absent[6]. The tissues must have become adapted to utilize an all-fat substrate, together with a small amount of endogenous protein. In view of the accumulation of liver glycogen, it is possible that one mechanism of adaptation is a conversion of fatty acids to carbohydrate precursors which are stored in the liver as glycogen and later released as glucose into the blood for transport to the tissues. However, since Soskin and Levine[7] have demonstrated that glucose uptake by the tissues varies directly with the blood sugar concentration, the foregoing explanation receives little support from the present observation of a marked hypoglycaemia, indicating that glucose utilization in the fat-adapted rat is much reduced. Increased insulin secretion would enhance glucose utilization in hypoglycaemia, but it is generally held to be low under conditions of carbohydrate deprivation[4]. Therefore, there is apparently no large-scale conversion of fatty acids to glucose involving transport of the glucose by the blood. The accumulation of liver glycogen can be accounted for satisfactorily by gluconeogenesis from endogenous protein and by the glycerol moiety of the fat molecule.

A more likely explanation of the mechanism of adaptation is that carbohydrate formed from non-carbohydrate sources is spared as catabolism of fat as a fuel is increased, permitting the liver glycogen content to rise. The mechanism for maintaining a normal blood glucose-level may become less active due to relative disuse of glucose by the tissues, thus allowing hypoglycaemia to develop. The condition may be compared to that prevailing in the normal ruminant, in which a low blood sugar-level may be attributed to relative disuse of glucose as a fuel because of its replacement, or partial replacement, by the volatile fatty acids produced in ruminant digestion. Apparently, even in the non-ruminant animal, provided there is a suitable period of adaptation, brain tissue is able to survive in the presence of a very low blood sugar-level (several results as low as 25 mgm. per 100 ml. have been observed in these experiments).

It is clear that hypoglycæmia does not always stimulate glycogenolysis. If the maintenance of the blood sugar in the normal animal depends on an enzymic mass-action mechanism, then under conditions of fat adaptation where an inverse relation between liver glycogen and blood sugar concentration prevails, there must be a metabolic block in the conversion of glycogen to glucose in the liver. The possible nature of the block may be a reduction in activity of glucose-6-phosphatase, since hypoglycæmia in the presence of reserves of liver glycogen is characteristic of glycogen storage (von Gierke's) disease, in which there is a deficiency of glucose-6-phosphatase[8].

Pterin Synthesis in the Amphibian Neural Crest Cell

A LARGE amount of fluorescent substances of pterin type has been known to exist in the coloured skin of amphibians and they were shown to accumulate in chromatophores such as melanophores and xanthophores (allophores), as in the bull-frog[1]. During the development, pterins appear simultaneously with the pigmentation in chromatophores[2]. Moreover, certain substances of pterin type have been reported to accelerate the *in vitro* formation of Dopa-melanin[3,4]. These facts suggest an intimate relation between the pterins and pigment formation in chromatophores. To analyse such a relation, it is desirable to know where pterins are synthesized in the course of embryonic development. The present experiment was carried out to ascertain the capacity of pterin synthesis in the pro-pigment cells of urodelan embryos. Pterins were extracted with 70 per cent ethanol and chromatographed on paper using the following solvents: *n*-propanol/1 per cent ammonia (2 : 1), *n*-butanol/acetic acid/water (4 : 1 : 1) and 5 per cent acetic acid.

Pterin Fractions in the Middle Neurula and Larva. As a preliminary experiment, qualitative determinations were made of pterins in the neurula, where pigment-cells had not yet differentiated, and in the larva, having well-developed melanophores and xanthophores in the trunk area. 30 intact middle neurulæ of *Hynobius nigrescens* (a salamander, Usui and Hamasaki's table, stage 17[5]), 50 intact middle neurulæ of *Triturus pyrrhogaster* (a newt, Okada and Ichikawa's table, stage 18[6]), trunk skins of 15 *Hynobius* larvæ at fore-limb-bud stage (stage 41–43), and 15 intact *Triturus* larvæ at fore-limb-bud stage (stage 37–38) were tested. Pterins were not found in the intact embryos at the middle neurula stage of either species, so naturally they were absent from the neural crest cells and the presumptive epidermis at that stage. At the fore-limb-bud stage, 2-amino-4-hydroxy-6-(1′,2′-dihydroxypropyl)-pteridine (biopterin[7]), 2-amino-4-hydroxypteridine, rhacophoro-jaune[8] (the same or similar with the 'sepia-pterine'[9] in *Drosophila*), *iso*xanthopterin, and 2-amino-4-hydroxypteridine-6-carboxylic acid occurred in both species. Of these five substances, rhacophoro-jaune and 2-amino-4-hydroxypteridine-6-carboxylic acid were found in abundance in both animals. In *Hynobius*, biopterin and *iso*xanthopterin were abundant, while there was only a small quantity of 2-amino-4-hydroxypteridine. In *Triturus*, on the contrary, biopterin, and especially *iso*xanthopterin, were much less, but 2-amino-4-hydroxypteridine was very abundant.

Pterin Synthesis in the Neural Crest Explant Enclosed in the Presumptive Epidermis. A small fragment of the trunk neural crest of the middle neurula was enclosed in the presumptive epidermis of the same embryo to ensure the sufficient differentiation of pigment cells. The epidermal explant without the neural crest served as a control. As a culture medium, Holtfreter's saline solution was used in order to avoid the additional complicating influences on pigmentation and pterin synthesis expected to occur in the explant. Each explant was cultured up to the stage where melanophores and xanthophores developed in the trunk region of the intact larvæ of the same breed (*Hynobius*, stage 41–43, 8 days at about 22°; *Triturus*, stage 37–38, 14 days at about 16°). 18–30 explants were used in each experiment. Whereas the explant with a neural crest had well-developed melanophores and xanthophores as in the intact embryos, the control epidermal explant was completely lacking in chromatophores. The fluorescent substances of pterin type were present in the former, and absent in the latter. Rhacophoro-jaune and 2-amino-4-hydroxypteridine-6-carboxylic acid were plentiful in both *Hynobius* and *Triturus* explants. Biopterin and *iso*xanthopterin were in much greater amount in *Hynobius*, and 2-amino-4-hydroxypteridine was abundant in *Triturus*. These quantitative relations of pterins in each explant were quite comparable with those found in intact larvæ of the respective species.

Hanging-drop Culture of Trunk Neural Crest. The pigmentation of chromatophores has been shown to be influenced by the surrounding epidermis in the field of experimental embryology. The synthesis of pterins in an explant, then, might be realized by the co-operation of epidermis, not by the pro-pigment cell itself. The fact that the epidermis had an indispensable role in the pterin formation was demonstrated in the following experiment. A small fragment of trunk neural crest of *Hynobius* middle neurula (stage 17) was cultured in Holtfreter's solution for 8–11 days at about 25° (stage 41–43 in controls). The melanophores and xanthophores in the explant showed little retardation as to the stage of pigmentation, but many of these pigmented poorly compared with those of the intact embryo. All kinds of fluorescent substances found in the intact larva at that stage were detected in these explants, although no quantitative results were obtained.

These results indicated clearly that the fluorescent substances of pterin type found in the intact larvæ of *Hynobius* and *Triturus* were synthesized in the pro-pigment cells in the process of their differentiation. This may strongly suggest that the simultaneous appearance of the pigmentation and pterins during the chromatophore differentiation is an expression of the inseparable relation of the two. However, this does not necessarily mean that all pterins found in intact larvæ are formed in the pro-pigment cells during pigmentation. In fact, a very small but perceptible amount of fluorescent substances of pterin type is found usually in larval and adult tissues other than skin. Whether these small quantities of pterins are derived from pigment cells, or synthesized *in situ*, or even supplied by way of nutrition, remains to be settled.

We wish to thank Prof. Adrien Albert of the Australian National University for his assistance in the preparation of this manuscript.

PHYSIOLOGY

Effect of Cortisone on Degenerating Nerve Fibres in Birds

THE observation that the usual appearance of the Marchi stage of Wallerian nerve fibre degeneration in experimental material is strikingly altered by cortisone acetate (Pfizer, Ltd.) led us to try to discover whether cortisone would also alter in any way the effects of tri*ortho*cresyl phosphate poisoning, which are usually most apparent in the myelin sheaths of nerve fibres. Our results so far seem encouraging. A single application of tri*ortho*cresyl phosphate painted on the combs of hens (the dose being 0·1 c.c. per kgm. body-weight) invariably causes general symptoms of intoxication and paralysis in the legs after 8–25 days[1]. The administration of 25 mgm. of cortisone by mouth three days before the application of tri*ortho*cresyl phosphate and further doses of 25 mgm. every third day thereafter in all cases prevented the onset of paralysis and reduced the other general symptoms. Even if the administration of cortisone was delayed until the hens were severely stricken by the poison, its beneficial effects were still apparent, for the general condition of the birds rapidly improved, they began to feed avidly, and the paralysis was reduced to a mild state of postural imbalance. Similar results were obtained if the dose of tri*ortho*cresyl phosphate was increased to 0·15 c.c./kgm.

In view of the outbreak of tri*ortho*cresyl phosphate poisoning in Morocco last year involving 10,000 people, these preliminary results may be of assistance in efforts to treat the crippled victims.

Potentiation of Contractility in the Heart Muscle of the Rat and Some Other Mammals

THE steady-state amplitude of rhythmical myocardial contractions reached after the period of 'staircase' varies regularly with the frequency, following a typical curve in most animal species: it decreases at first, at very low frequencies, passes through a minimum (least favourable frequency), then at higher rates it increases up to a maximum (optimal frequency), to decrease again, at still higher rates, up to the limit of frequency which the preparation can follow[1]. The shape of the curve is, however, much modified in the rat in comparison with that of other species, the initial decrease of contractility being very marked, while the following increase to the optimum is, on the contrary, only small or absent[2]. In contrast to the classical staircase phenomenon, an inverted staircase (decrease of contraction) has been observed in the auricular or ventricular strips of the rat after a period of rest, or after the transition from a lower to a higher rate of stimulation[3].

These variations of contractility as a function of frequency may be interpreted as resulting from the interaction of two factors or effects, varying in opposite senses with the interval between the succeeding contractions[1]. One, namely, augmentation of amplitude on lengthening and diminution on shortening of preceding interval, has been called 'restitution'; the other, an augmenting effect on the shortening of the previous interval, has been termed 'potentiation' (Fig. 1). The 'potentiation' effect occurs only at short (least favourable) intervals, is cumulative and forms, in our interpretation, the common basis of the positive staircase, of the post-stimulation and post-extrasystolic potentiation, as well as of the steady-state amplitude variations. The terms 'restitution' and 'potentiation' are meant to be provisional, without any prejudice concerning the true nature of each of these effects, which may be dissociated and followed separately in their variation as a function of frequency[4] (Fig. 1).

The restitution effect may be measured by the change of amplitude in a number of single premature and delayed beats, intercalated in regular steady-state contractions. The 'potentiation' effect is indicated by the augmentation of the contraction next to the premature one (conditioning contraction), provided it follows at the basal interval. This point is very important, since in the case of an extra beat followed by a longer (compensatory) interval as well as in that of an intrapolated beat followed by a shorter interval, the change of contractility of the next contraction is due to both effects. The immediate return to the previous (basal) interval maintains, however, the 'restitution' effect constant, so that only a pure 'potentiation' effect appears. (For details of technique see our previous paper[4].)

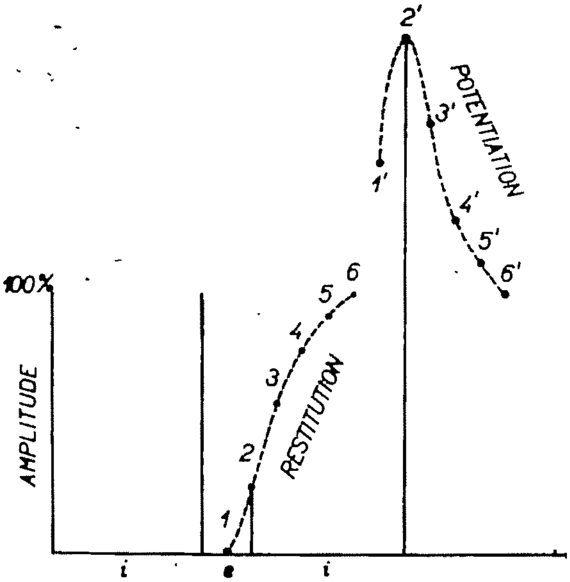

Fig. 1. Separate evolution of the 'restitution' and 'potentiation' effects. 100 per cent represents basal amplitude reached after a period of regular stimulation; i, interval between successive regular stimuli; e, interval of a premature beat conditioning potentiation of the next contraction. Amplitudes of premature beats following different pre-extrasystolic intervals 1–6 form a curve indicating the degree of restitution of contractility. Amplitudes of the respective post-extrasystolic beats 1′–6′ form a typical curve of 'potentiation'. Left auricle of the dog, 30° C.; basal rate, 60 beats/min.

Comparison of results of experiments on 78 isolated left auricles of the dog (15), cat (3), rabbit (16), guinea pig (20) and rat (24) shows that: (1) the restitution effect has a markedly steeper course in the rat than in the other mammals examined; (2) the potentiation effect in the rat myocardium is very small and occurs only when the premature beat is elicited at a very short interval (Fig. 2).

Also reactions of rat myocardium to some drugs (for example, strophantin) differ from those of other species[5]. Experiments on this matter are in progress in our laboratory and will be reported later.

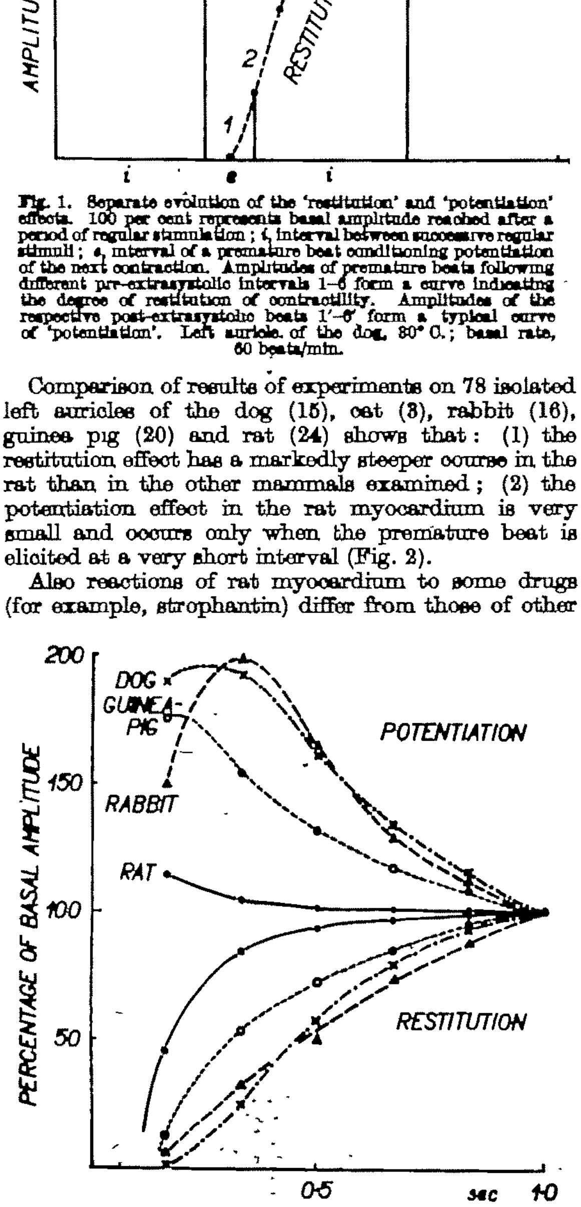

Fig. 2. Variations of the 'restitution' and post-extrasystolic potentiation effects as a function of the conditioning interval on the rat auricle compared with those of some other mammalian species. Values for the cat auricle, being very close to those of the guinea pig, have not been included. Individual experiments. Temperature, 30° C.; basal rate, 60 beats/min.

The differences described in the behaviour of amplitude in relation to the interval between contractions show clearly that rat heart muscle cannot be considered as representative of mammalian myocardium, and no direct conclusions from experiments with it can be drawn for the physiology of contractility of the heart muscle of other mammals and especially man. The distinction and dissociation of two effects underlying the relationship of the rhythm to the contractile force may prove useful in the analysis of these complex but remarkably regular phenomena.

Potassium Tolerance Tests in South Indian People

POTASSIUM tolerance in man was studied by Zwemer and Truskowski[1] in relation to adrenal gland activity. After an oral intake of 20 mgm. of potassium chloride/kgm. body-weight, no rise of the plasma potassium-level is observed in normal Europeans, while a rise of 30 per cent or more is established in cases of cortical insufficiency. Accordingly, Henrotte (unpublished work) found a mean rise of 6 per cent in 12 healthy Belgian students. However, in Dakar, Leschi[2] obtained, in the same experimental conditions, an average of 4·1 ± 4·8 and 13 ± 8·1 per cent, respectively, for the maximal rise in potassium of 6 Europeans and 32 Negroes of male sex. Consequently, I suggest the occurrence of a lower cortical metabolism in Negroes and its relation with the pigmentation.

Similar experiments have been undertaken in Madras with 26 Indians and 9 White Europeans or Americans, all male. The potassium tolerance tests were conducted according to Leschi's method[2], before breakfast and early in the morning, the room temperature being 29–32° C. (with 60–80 per cent humidity) throughout all the experiments. After the intake of potassium chloride, blood samples were taken every 20 min. for 1 hr. The potassium was determined in the plasma by flame spectophotometry. The maximal rise observed during the test and expressed in percentage of the fasting-level was as an average equal to 12·4 ± 7·5 per cent for White people and to 14 3 ± 7·3 for Indians. The differences between Indians, Africans and White people of Madras are not significant. In the case of the last-named, the maximum rise in potassium bears a direct relationship to the length of stay in Madras (Fig. 1), the relation being significant at the level of 5 per cent.

Our results indicate the occurrence of a climatic factor in the variation of tolerance of potassium in man, that is, of human cortex activity, rather than a racial factor. Our findings are confirmed by a fall of 27·3 per cent in 17-ketosteroid excretion observed

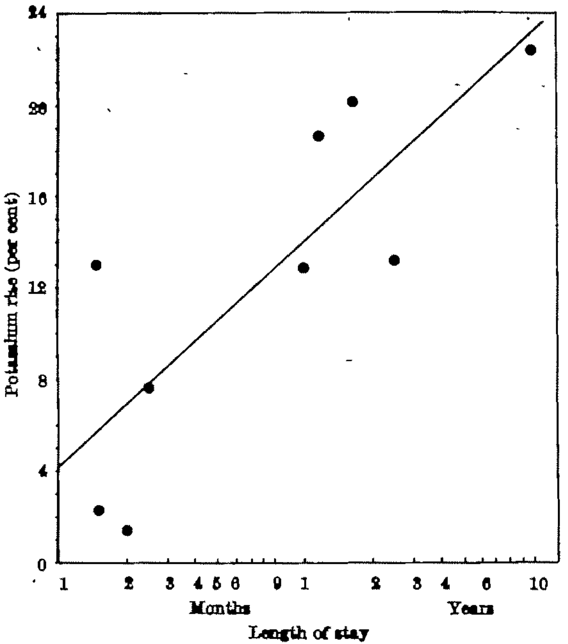

Fig. 1. Ordinate, maximal potassium rise observed during the test in White people and expressed in percentage of the fasting potassium-level; abscissa, length of stay in Madras expressed in months on a logarithmic scale

By Robinson *et al.*[3] during the hot season in Australian White people. On the contrary, urinary 17-ketosteroids determinations carried out in India[4] and in Africa[5] with both indigenous and Europeans show much larger values in Europeans than in the two melanodermic races. The discrepancy between these latter results and ours could be explained by the fact that urinary 17-ketosteroids represent the amount of cortical hormone excreted rather than the real activity of the gland. Relation between excretion of steroids and their amount in the blood could vary in the same conditions and should be further investigated.

We acknowledge with thanks the technical facilities provided for our work by Profs. K. P. Anandan and N. Verghese.

Effect of the Cations of the Lyotropic Series on the Tension of Vascular Muscle

It has been found that, in experimental corticosteroid-induced hypertension, the content of potassium in the vascular wall increases according to the hypertension[1]. On the other hand, experiments *in vitro* with carotis strips showed that an increase of the potassium concentration of the bath solution causes a rise in tension which runs different from that of smooth muscle in the colon. The difference is due to the fact that potassium penetrates into the vascular muscle but not into the smooth muscle of the colon. In the vascular muscle the tension rises parallel to the intracellular potassium and remains constant as long as the latter is not diminished[2]. The relation between $[K]_i$ and the resting potential as well as between the resting potential and the change of length in muscle (contraction) are rather well known and will be discussed in another communication. There arises the problem of the effect of the intracellular potassium. The influence of other monovalent cations of the lyotropic series (caesium, rubidium, sodium) on the tension of vascular muscle has been investigated, too, under the same conditions as the potassium effect. The results are illustrated in Figs. 1–3. They show: (1) The threshold concentration which induces a rise in tension of the vascular muscle increases with the diameter of the ion (caesium, 5 m*M*; rubidium, 10 m*M*; potassium, 30 m*M*). To obtain an increase of the tension by means of sodium chloride, the sodium concentration of the Tyrode solution has to be augmented by 140 m*M*. At this concentration, the increase in tension can be effected merely by the high osmotic pressure, as it is in the case of sucrose, for example. (2) At equal concentrations of alkalichlorides, the increase in tension is smaller with increasing diameter of the ions (Fig. 3). (3) At higher caesium concentration, the increase of tension is not continuous.

If the same concentration either of potassium or of caesium is used, the amount of caesium which penetrates into the vessel wall is only 42·5 per cent of the amount of the penetrating potassium. The fact that for caesium the threshold concentration which causes

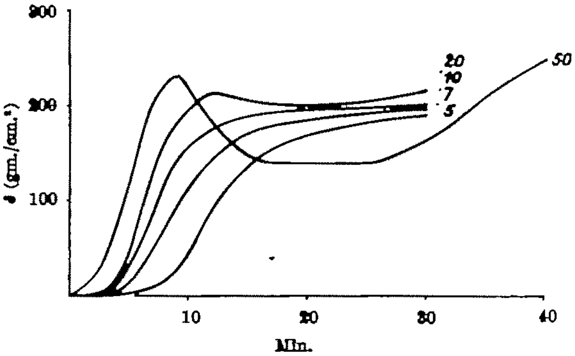

Fig. 1. Rise of tension with different concentrations of caesium chloride. Figures on the right indicate m*M* caesium. Initial tension, 310–335 gm./cm.^{2}

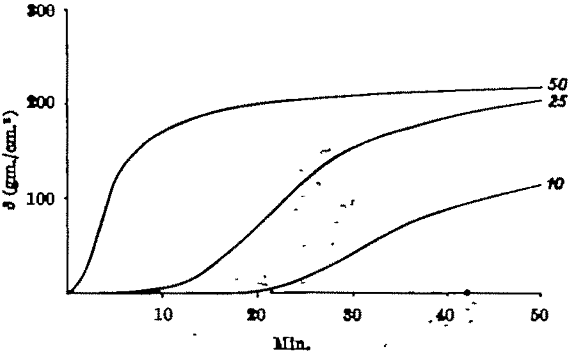

Fig. 2. The same as Fig. 1 with rubidium chloride

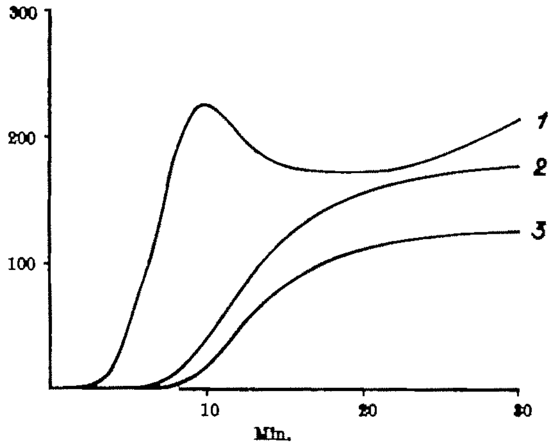

Fig. 3. Rise of tension with caesium chloride 30 mM (1), rubidium chloride 30 mM (2), potassium chloride 30 mM (3). Initial tension 325 gm./cm.²

an increase of tension is of 5 mM only might be considered as especially interesting. Since the permeability constant for caesium is smaller than for potassium and since the muscle fibre releases no potassium during the increase of the tension, contrary to what usually happens in contractures, we assume that the increase in tension is effected by the caesium which penetrates into the muscle fibre. The rise in tension after the extracellular potassium has been increased as well as the recovering after it has been decreased take place in a medium free both of oxygen and of glucose. These results led us to the working hypothesis that the increase of tension is caused by the discharge of a protein anion by means of a lyotropic cation. As it is known, the smaller the diameter of the monovalent cation, the closer is its approach to the protein and the stronger its attraction. To evidence the same change of state of the protein, more potassium is used than caesium (see threshold value). The tension is maintained by the new state of the protein, that is, without use of energy.

Visco-elastic Behaviour of Blood Vessels of the Muscular Type

It was shown in the previous communication that the 'threshold-concentration' of ions of the lyotropic group which produce a rise in tension of the muscles in a vessel increases with increasing diameter of the lyotropic ion. Because this process also works in the absence of oxygen, we might assume that a discharge of protein ions takes place which causes a change of state. We presume that this change of state also produces a change in the visco-elastic behaviour.

The visco-elastic behaviour of ring-shaped or rectangular pieces of a cow carotis has been established with an oscillographic method using periodical stretches (frequency 1–1·8 cycles/sec.). The stress-strain relation (Young's modulus), as well as the phase shift between these, could be measured with a method described in an earlier publication[1] and now considerably improved. During the measurements, the samples of vessels were immersed in Tyrode's solution at body temperature. The questions treated were the following: (1) the influence of potassium (60–70 mM); (2) the influence of suprarenin; (3) the influence of electrical excitation on Young's modulus and on the viscosity constant η or its product $\omega\eta$ with the angular frequency, which can be computed from the phase shift between stress and strain and Young's modulus. The heat dissipated in the sample can then be found from $\omega\eta$.

(The heat generated by friction can be found as follows: the resistance to stretch for a piece of arterial wall of length l and cross-section q will be $R = \eta q/l$, where η is the viscosity constant. For a periodic stretch we might put $l = l_0 + \Delta l.\sin(\omega t)$. To overcome the friction, we need the force $F = R\, dl/dt$. The work done during a period is found by integration:

$$\int R.\frac{dl}{dt}.dl = \pi.R.\omega(\Delta l)^2$$

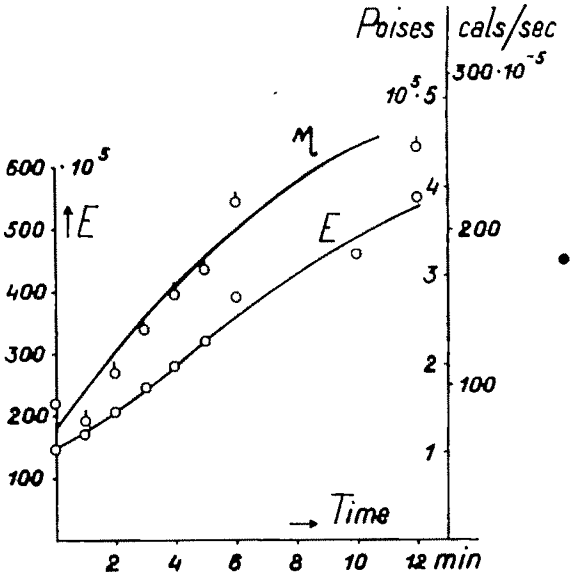

Fig. 1. Carotis (cow), stretch perpendicular to axis of vessel. Effect of potassium (70 mM) on the dynamic modulus of elasticity E and the viscosity constant η. Abscissa, time (min.); ordinates, left side Young's modulus E in dynes/cm.²; right side left scale, viscosity constant in poises; right side right scale, heat dissipated in a cube of 1 c.c. with an amplitude of stretch of 0 05 cm. due to internal friction. Angular frequency, ω = 13 9

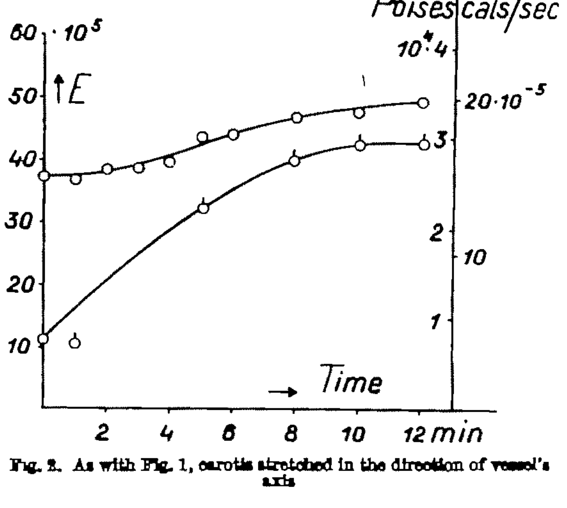

Fig. 2. As with Fig. 1, carotis stretched in the direction of vessel's axis

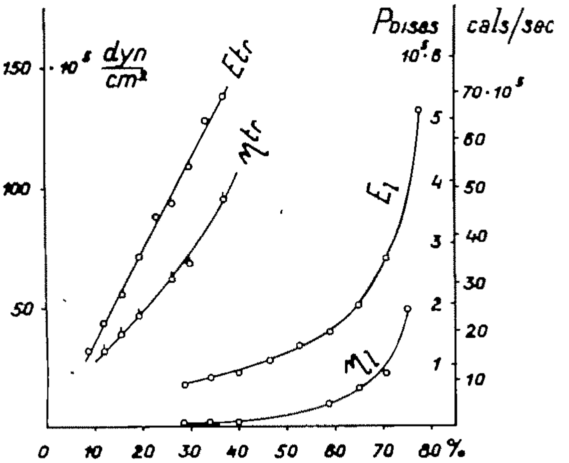

Fig. 3. Dynamic modulus of elasticity E_{tr} and viscosity η_{tr} in transversal, E_l and η_l in longitudinal direction as functions of relative stretch (cow carotis). External scale to the right gives the heat dissipated in a cube of 1 c.c. with an amplitude of stretch of 0·05 cm. due to internal friction. Angular frequency, $\omega = 6·5$

For the power we obtain $P = (\omega\eta).\omega(\Delta l)^2 q/(2l)$. The product $\omega\eta$ is the quantity obtained by the experiment. It is of the same dimension as Young's modulus. In order to get a more concrete picture, we have calculated the heat generated in a cube of material of 1 c.c., where the amplitude Δl of stretch is taken to be 0·05 cm. For this specific assumption we obtain $H_{sp.} = (\omega^2\eta).0·298 \times 10^{-10}$ cal./sec.)

Potassium always brought about a considerable increase of tension and of Young's modulus perpendicular to the axis of the vessel, which reached their maximal value within a range of time of 12 min. after the administration of potassium. In some cases, according to [K] Young's modulus rose to about four times its original value and remained constant after this time. The internal energy dissipation increased in the same time.

If we carried out the same experiment with rectangular samples, one cut perpendicularly to, and the other in the direction of, the vessel's axis, we obtained an increase of Young's modulus from 15×10^6 to 55×10^6 dynes/cm.² in the first case (Fig. 1). η and the dissipated energy enhanced about at the same rate. Because only few muscle fibres run in the direction of the axis, we obtained in this direction an increase of Young's modulus only from $3·8 \times 10^6$ to $5·0 \times 10^6$ using the same initial stretch of 26 per cent (Fig. 2). The relative increase of the dissipated energy remained about the same as in the first case. In carrying out comparative measurements as mentioned here, care has to be taken that the experiments are performed with the same initial relative stretch, because the visco-elastic behaviour of vessels depends on it to a large extent. This we have illustrated with a set of experiments the results of which are given in Fig. 3.

When the immersion of 60–70 mM K was replaced by normal Tyrode's solution, the tension as well as Young's modulus dropped to the original value. Experiments with suprarenin and electrical excitation showed considerable increase in tension, but only a slight increase in Young's modulus. Skeletal muscle of frog (sartorius and musc. rect. abd.) showed no change in the visco-elastic behaviour either with potassium or with electrical excitation.

The importance of these results regarding the development of arterial tension in normal and in hypertensive individuals will be discussed in a further publication.

Osmotic Regulation in the Larvæ of some Euryhaline Diptera

The relationship between blood concentration and the external medium is known in only one salt-water dipteran, the larva of *Aedes detritus*[1,2]. During a recent study of a small salt-marsh, on the Northumberland coast, several euryhaline Diptera were investigated with regard to survival and blood regulation in sea-water media. Some of the results are briefly reported here.

Groups of 10 larvæ of *Ephydra riparia* were kept in shallow dishes containing media ranging in concentration from tap-water to sea-water evaporated to half its original volume. Larvæ were not fed during the course of experiments at room temperature (18–22° C.).

In tap water, and concentrations less than normal sea-water all of the larvæ survived; several pupated, and adults emerged successfully during the course of the experiments. In concentrations greater than normal sea-water some of the larvæ lost water, became shrunken in appearance, and eventually died. The majority survived for at least two weeks in sea-water equivalent to 8·0 per cent sodium chloride.

Blood samples from individual larvæ were taken after 7 days for micro-chloride and freezing-point depression measurements. Both are powerfully regulated (Fig. 1B) to a greater extent than in *Aedes detritus* in concentrated sea-water media[1]. As in

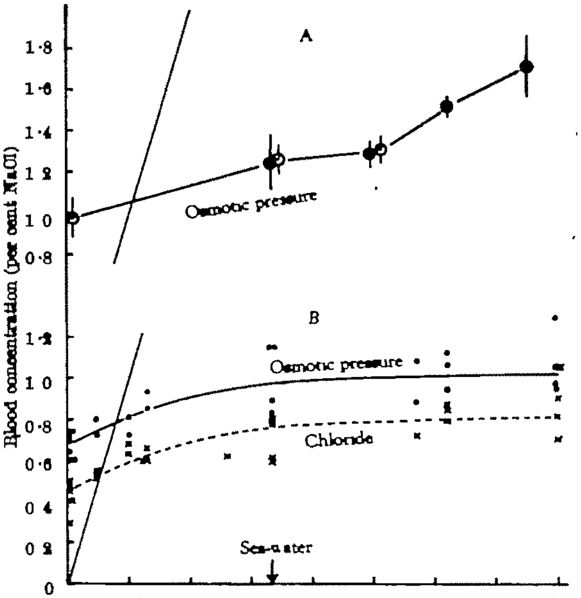

Fig. 1. Relation between osmotic pressure of the medium and of the blood in: *A*, *Cricotopus vitripennis*, typical form ● and var. *halophilus* ○, points mean of six larvæ, vertical lines extent of standard deviation; *B*, *Ephydra riparia*

			1·07	7·40	7·20
			1·30	7·84	8·20

A. detritus the slight but gradual increase in blood osmotic pressure is due to an increase in blood chloride concentration, which is relatively high and accounts for approximately 75 per cent of the total blood concentration.

Similar observations were made on larvæ of two varieties of *Cricotopus vitripennis* (Fig. 1A). The estuarine form var. *halophilus*, obtained from the salt-marsh, completed its life-cycle in concentrations less than 5·0 per cent sodium chloride. In higher concentrations of sea water nearly all the larvæ became shrunken in appearance and died within 4 days. Larvæ of the typical form were obtained from coastal rock-pools at high water mark. These larvæ survived direct transference from tap-water into sea-water equivalent to 7·5 per cent sodium chloride, in which the life-cycle was completed, and they showed no signs of loss of water in this concentration of sea-water. These observations suggest that the two forms of *C. vitripennis* may be physiologically distinct, although each form is well adapted to survive the range of salinity normally encountered in its habitat.

The degree of osmotic independence shown by larvæ of *A. detritus*, *E. riparia* and *C. vitripennis* can probably be achieved only by a considerable degree of impermeability to water and salts, and it is significant that they do not possess functional anal papillæ, which are characteristic of aquatic dipterous larvæ. Intake of salt-water through the gut is, however, likely to occur, and the larvæ must then elaborate a fluid in the rectum at least as concentrated as the external medium. Preliminary measurements of the freezing-point depression of rectal fluid obtained from larvæ of *E. riparia* show that this species can elaborate fluid considerably more concentrated than the medium (Table 1). Similar measurements were also made on larvæ of *Coelopa frigida* (Table 1), which live in wrack beds stranded at high tide-level. As in *A. detritus*[2], the ability of *C. frigida* to elaborate a fluid hyper-osmotic to the medium is not so well developed as in larvæ of *E. riparia*.

HÆMATOLOGY

Immuno-electrophoretic Demonstration of Precipitating Components in Sera from Pregnant Women

Smithies[1] and also Thornes[2] recently described the occurrence of certain serum proteins in sera from pregnant or recently pregnant women. According to Smithies[1], an α_2-globulin is present in sera from about 10 per cent of women in late pregnancy or shortly after delivery, and is demonstrable by means of starch-gel electrophoresis. Thornes[2], by means of gel-diffusion experiments, demonstrated serologically specific components in pregnancy sera by absorbing the immune serum prepared in rabbits with normal human serum. In each of 29 sera collected from patients during the last three months of pregnancy, he found this serologically distinct component. Immunization of rabbits with placental extracts made possible the demonstration of one to four different antigens serologically different from the serum proteins of normal sera, two of which were also found in sera from patients with abnormal tissue metabolism.

In order to study the possible occurrence of 'pregnancy-specific components', an antihuman immune serum, prepared in rabbits by immunizing with serum from patently normal blood donors, was absorbed with serum from one such blood donor by means of the intra-basin-gel absorption[3,4], and used to develop the immunoelectrophoretic pattern of sera from 7 women taken immediately after normal delivery. In five of these sera a precipitate in the fast α_1-globulin region was demonstrable (precipitate *A*). In two of these five sera also another precipitate (precipitate *B*) appeared in the slow α_2-β_1-globulin region.

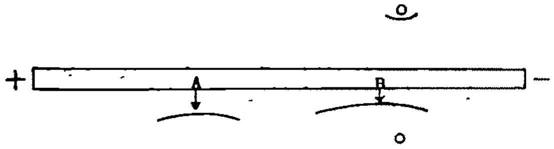

Fig. 1. Diagrammatic representation of presumed *C*-reactive protein precipitate (upper basin) and the 'pregnancy precipitates *A* and *B*' (lower basin) in immunoelectrophoresis

It was also found that some normal sera prevented the appearance of precipitates *A* and *B* or one of these components when used to absorb the immune serum in the intra-basin-gel absorption technique. This property of normal sera appears to be constant in the same individual for at least one year.

Sera from 20 normal subjects (males and females) and sera from 3 of 4 patients with diseases involving 'tissue destruction' did not give any precipitates against absorbed immune serum. The serum of one of these 4 patients did, however, give precipitate *A*. This serum also formed a precipitate against a commercially available *C*-reactive protein immune serum (Schieffelin, New York) in immunoelectrophoresis. This presumed *C*-reactive protein precipitate differed from the precipitates *A* and *B* in that it occupied different electrophoretic and diffusion positions, and its shape was different. The two pregnancy sera possessing both precipitates *A* and *B* did not show precipitate formation against *C*-reactive protein immune serum.

In conclusion, it can be stated that certain anti-human immune sera absorbed with selected normal sera give two electrophoretically different precipitates with some sera from recently pregnant women. Other 'pregnancy sera' when examined by the present technique[4] lack either both or one of these precipitates.

Precipitate formation between selected 'pregnancy sera' and absorbed immune serum will also distinguish between four types of normal sera, by their capacity of completely inhibiting the formation of visible precipitate, by inhibiting only one of these precipitates but not the other and finally by not inhibiting the formation of any of these 'pregnancy precipitates', when used as absorbing reactants of the immune serum.

We gratefully acknowledge the liberal supply of sera from the Department of Women's Diseases, Sabbatsberg Hospital, Stockholm.

Sickling Phenomenon in Deer

GULLIVER[1] described peculiarly shaped red cells in deer blood and Undritz[2] was able to produce these cells *in vitro* by passing oxygen through the blood. The cells looked remarkably like human sickle-cells. Gulliver examined three tropical deer: *Cervus mexicanus*, *Cervus reevesii* and *Cervus porcinus*. He also mentions a Persian deer, but its scientific name is not given. O'Rouke[3] investigated 178 deer in the United States and found 'sickle-cells' in 14. Undritz obtained positive results with the blood of *Cervus elaphus*, *Dama dama*, *Sambar* (*Rusa*), *Pseudaxis sika*, *Pseudaxis hortulorum*, *Axis axis*. The present investigation has been carried out with blood from *Elaphurus davidianus* (Père David deer). No sickle-cells could be produced with the blood of *Rangifer tarandus* (reindeer), *Alces alces* (elk), and *Cervus canadiensis* (Wapiti deer).

In man, sickle-cells are produced when erythrocytes containing the abnormal hæmoglobin *S* are deoxygenated. This hæmoglobin is relatively insoluble in the reduced state and on deoxygenation it forms intracellular tactoids which stretch the cell envelope and give the cell its bizarre sickle shape. It might seem that in the deer the effect is just the opposite, particularly because the sickling produced by treatment with oxygen can be reversed by addition of the reducing agents $NaHSO_3$ and $Na_2S_2O_4$. However, we can now report that sickling of deer cells occurs equally well when the blood is saturated with nitrogen or carbon monoxide but not with carbon dioxide. The effect of oxygen, nitrogen and carbon monoxide is due to a replacement of the carbon dioxide which causes as it were a 'respiratory alkalosis'. The reducing agents are acid, and hence they reverse the alkaline *p*H and the sickling.

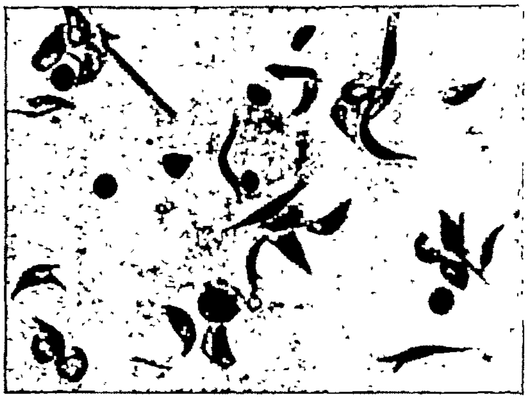

Fig. 1. Red cells of *Elaphurus davidianus* (Père David Deer) at *p*H 7·8. (× 750). Heparinized blood was mixed with an equal volume of 0·1 *N* Sørensen phosphate buffer *p*H 7·8 and the mixture was saturated with carbon monoxide

When deer cells are suspended in 0·1 *N* KH_2PO_4, no sickling can be produced by gassing with oxygen, and when they are suspended in 0·1 *N* Na_2HPO_4 they sickle without any further treatment. There is a relatively sharp transition from the normal to the sickle-shape between *p*H 7·0 and *p*H 7·5; some sickle-cells can already be noted at *p*H 7·2 and nearly all cells are sickled at *p*H 7·4.

When the solubilities of oxygen, of reduced and of carbon monoxide hæmoglobin are compared, they

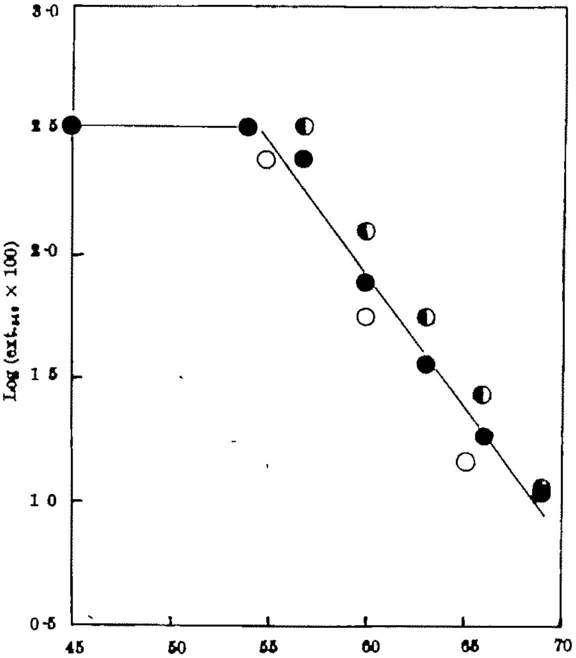

Fig. 2. Solubility in ammonium sulphate solutions of oxyhæmoglobin (○), reduced hæmoglobin (●) and carboxyhæmoglobin (◐) of *Elaphurus davidianus* (Père David Deer). To 9·5 ml. $(NH_4)_2SO_4$ solution of increasing saturation were added 0·5 ml. 0·5 per cent deer hæmoglobin. Reduced hæmoglobin was produced by addition of 30 mgm. $Na_2S_2O_4$. After mixing, the 10 ml. samples were kept in a stoppered vessel for several hours at 23·5° C. and then filtered. The hæmoglobin filtrate was converted into cyanmethæmoglobin and measured colorimetrically. It will be seen that there is no significant difference in solubility of the three hæmoglobins

are seen to differ little, and indeed Fig. 2 shows that the values for reduced deer hæmoglobin lie between those for oxygen and carbon monoxide hæmoglobin.

There is no significant difference in the solubility at increasing concentrations of phosphate buffers of pH 7 and pH 8. It was noticeable in these tests as well as in those described in Fig. 2 that precipitated oxyhæmoglobin which was left on the filter paper after filtration was rapidly transformed into methæmoglobin, whereas this was not so in the case of the human hæmoglobin controls. Deer hæmoglobin is oxidized by $K_3Fe(CN)_6$ about twice as fast as human hæmoglobin.

We wish to thank Dr. E. Lang, director of the Basle Zoo, for kindly supplying the deer blood.

Platelet-Count Differences in Blood of the Rabbit Right and Left Heart Ventricles

THIS work was undertaken in an attempt to determine whether a difference could be demonstrated in the platelet counts of the blood of the rabbit right and left heart ventricles. That such a difference might occur suggested itself from the recent work of Sharnoff and Kim[1,2], which studies revealed that megakaryocytes are present normally in the lung blood vessels of all mammals, where they appear to break up in the pulmonary capillary anastomoses into platelets. Therefore, it was postulated that if the lung vessels were a possible site of platelet formation, the blood of the left heart ventricle could contain a higher number of platelets than that of the right ventricle. The difference in number of platelets, it was believed, would depend only on the number of megakaryocytes present and breaking up at any one time in the lung vessels.

Twenty young female Belgian hares weighing 2–4 lb. were killed by rapid air embolism and within 1 min. the chest cavity was opened and the heart exposed. Blood samples were obtained by needle aspiration from both ventricles while the heart was still in ventricular flutter. The blood was preserved with 'Versene' (disodium salt of ethylenedinitrotetra-acetic acid, Eastman-Kodak). Indirect platelet counts were performed in duplicate by Fonio's method and averaged. Erythrocytes were determined by the counting chamber method. The animals were raised and maintained under outdoor conditions and temperatures except for short periods when unheated housing was provided. The work was begun in August 1958 and completed in February 1959. On this basis the animals could be divided into two equal groups of 10 each. The first group of 10 was studied during warm and mild autumn weather. The second group was studied during the winter months. For convenience the groups are designated accordingly as summer and winter animals.

A striking difference in platelet counts of the blood of the right and left ventricles was noted with two exceptions in the winter animals. No essential difference was found in the platelet counts of the blood of both ventricles of the summer animals and in the two exceptions of the winter animals. The winter animals, including the two exceptions, revealed the platelet counts of the right ventricle averaging 245,000 per cm.³, while the left ventricle blood revealed platelet counts averaging 408,000 per cm.³. Average platelet counts of the right and left ventricle bloods of the summer animals were respectively 256,000 and 254,000 per cm.³ (Fig. 1). Erythrocyte counts of the 20 animals averaged 5·4 million per cm.³.

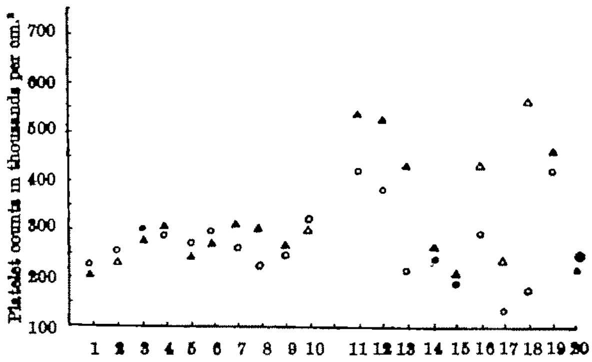

Fig. 1. △, Left ventricle; ○, right ventricle. 1–10, Summer animals; 11–20, winter animals

These studies indicate that from the lung vascular system there is added to the blood of the winter animals a significant number of platelets. This would tend to substantiate the earlier suggestion of Sharnoff and Kim[1] that the lung vessels may be a significant site of platelet formation. The significant increase of platelets in the winter animals in this study also complements the observation by Sharnoff and Kim[2] in an earlier study where significantly high numbers of platelets were observed in the peripheral blood of winter control animals compared to summer control animals.

It is suggested that the source of the increased platelets are the pulmonary megakaryocytes usually present in the lung vessels. It is also suggested that the stress of winter cold may stimulate an increase in number of pulmonary megakaryocytes which on the further stress of killing the animals break up rapidly into platelets. It may also be postulated that where no significant increase in platelets occurs the lung vessels may have a low number of megakaryocytes.

This work also corroborates earlier findings that the lungs may be a source of platelets. Howell and Donahue[3] in dog lung perfusion studies, and later Bierman[4] in human studies, recorded such evidence. In this report, however, a more rational explanation of this phenomenon is presented. This is further supported by the histological observations of Sharnoff[5] revealing that the pulmonary megakaryocytes are moulded and broken asunder in the pulmonary capillaries and their anastomoses and thus emerge as casts of the capillaries and at times, therefore, appear in the peripheral blood as long platelets.

PATHOLOGY

Absence of Local Cytotoxic Change in Man from Griseofulvin

WITH the importance of griseofulvin in the treatment of superficial fungous infections, it is imperative to know more about the toxic reactions especially if treatment is prolonged. Since the significant studies of Paget and Walpole[1] on the interference with mitosis under massive parenteral administration of griseofulvin in rats, there has been continued interest in investigations of this phase of reaction in man. Our purpose was to develop a technique for studying possible local cytotoxic reactions in man from locally deposited griseofulvin.

Supersaturated solutions of microcrystalline griseofulvin were prepared in saline, sterilized by autoclaving, and after vigorous agitation, 0·1–0·2 ml. was injected into 14 patients into areas of normal skin of the back and arm and into the scalp in the occiput area. In many instances the injection site was tatooed with indian ink to localize the crystal mass. Controls had been done previously with indian ink particles. In addition, in 6 patients, griseofulvin was injected into three basal cell tumours, one squamous malignancy, one melanoma and one malignant lymphoma. In four additional subjects, a lotion containing 1 per cent griseofulvin was rubbed daily for three weeks into basal cell carcinoma, squamous cell carcinoma, and into the so-called precancerous senile keratosis. To detect any anti-inflammatory activity of griseofulvin, saline suspensions of griseofulvin were injected repeatedly into spots of psoriasis, and neurodermatitis.

No local anti-inflammatory property could be detected. In normal skin, the biopsies were taken at intervals ranging from 1 hr. to three months after local injection and were studied in frozen section and in prepared sections with routine hæmatoxylin–eosin, toluidine blue *p*H 6, periodic acid–Schiff, Feulgen stains. The frozen sections were examined under the polarizing microscope to detect the depots in the dermis of the insoluble crystals. After a period of several days, crystals could not be detected under the polarizing microscope. In three instances, a bioassay of the skin extract was performed to detect antifungal activity of the tissue. In all these experiments, there were no spectrofluorometric determinations for griseofulvin in extracts of the injected skin. A total of 30 injections of griseofulvin was given.

In brief, there was only occasionally a mild foreign-body reaction of non-specific type about the depot of crystals. This subsided rapidly, usually within three or four days, and then no demonstrable inflammatory activity could be detected except occasional perivascular lymphocytic infiltrate. In one patient, after three weeks there were still a few histiocytes and foreign-body giant cells. There was no change in mitosis in any portion of the epidermis surrounding this, or in any portion of the adjacent hair follicle. In only one experiment, vacuolization of the cells in the adjacent portion of the hair follicle was found. In one instance, three months after injection, no change was found. In all the human tumour experiments there was no effect in either retardation or acceleration of the tumour growth, nor any demonstrable local effect on the individual tumour cell. In clinical observation[2] of a year's experience with oral griseofulvin in fungous therapy programme on more than 400 patients, there has been no evidence of any effect upon associated skin tumours, including basal cell, squamous cell and melanomas. In two patients with melanomas, griseofulvin was given in dosages of 2–4 gm. There is no information available on the effect on any associated internal visceral tumours other than the melanomas.

To amplify this study in the Department, the effect of griseofulvin in animal tumour experiments was initiated.

Griseofulvin crystals were furnished by Dr. G. Kenneth Hawkins, Clinical Research Division, Schering Corporation, Bloomfield, New Jersey.

Tumour-promoting Effect of Excessively Large Doses of Oral Griseofulvin on Tumours Induced in Mice by Methylcholanthrene

LARGE intravenous doses of griseofulvin in rats have been found to arrest mitosis in metaphase in certain organs, for example, bone marrow, seminal epithelium and intestinal epithelium. We postulated that since griseofulvin taken orally is soon found in the keratin layer of the skin, there might be an antimitotic effect with a delay in the production, and a reduction in the number, of tumours that would be produced by applications of methylcholanthrene to the epidermis of mice. A pilot experiment was performed which gave quite unexpected results.

White Swiss male mice of 24–28 gm. per mouse were divided into five groups. One drop of 0·5 per cent 3-methylcholanthrene in acetone was applied twice weekly for 4 weeks to the lower back of the mice of groups 1, 2 and 3.

Group 1 consisted of 20 mice receiving standard mouse food and having applications of methylcholanthrene. None of the 20 mice had any tumours formed as late as 12 weeks after the start of methylcholanthrene applications.

Group 2 consisted of 10 mice receiving a 1 per cent griseofulvin mouse food mixture for 6 weeks prior to, during and after the applications of methylcholanthrene. This group showed 5 of the 10 mice to have papillomas formed at the end of the first month of applications of methylcholanthrene. By the end of the second month of the experiment, 6 of

10 mice had tumours formed, and in several cases multiple tumours were seen. A few of these tumour growths were biopsied at the ninth week of the experiment and showed extraordinary hyperkeratosis and much mitotic activity. One was judged to be premalignant.

Group 3 consisted of 10 mice receiving 0·5 per cent griseofulvin mouse food mixture for 6 weeks prior to, during and after the applications of methylcholanthrene. At the end of a month, one of 10 mice showed a neoplasm which was biopsied at the ninth week and proved to be a well-differentiated epidermoid carcinoma. At the end of two months, 2 of 10 mice had tumour growths.

Group 4 consisted of 10 mice receiving a 1 per cent griseofulvin food mixture as long as group 2, and group 5 consisted of 10 mice receiving a 0·5 per cent griseofulvin food mixture as long as group 3. No methylcholanthrene was applied to these groups. No tumour growths have appeared in groups 4 and 5, which have received griseofulvin for 18 weeks.

We are repeating this experiment in larger groups of animals at the present time, and at the sixth week of the new experiment find that we are obtaining similar results. An addition to the experiment showed no tumours to have formed in mice receiving either a 0·01 per cent or a 0·1 per cent griseofulvin food mixture and having methylcholanthrene applications twice weekly for 6 weeks.

It is emphasized that the dosage used in the 1 per cent experiments was approximately 100 times that used in man.

This experiment was sponsored through the United States National Institutes of Health, Division of Research Grant *CY*-5071 (*A*). Griseofulvin powder was obtained from Dr. Clarence Denton, Division of Clinical Investigation, McNeil Laboratories, Inc., and Dr. G. Kenneth Hawkins, Clinical Research Division, Schering Corporation.

ANATOMY

Presence of a Pituitary Portal System in Elasmobranchs

Since the discovery in the 1930's of the pituitary portal system in man, a similar system has been described in a large number of vertebrates, from amphibians to mammals[1]. Green did not notice a portal system in fishes, but suggests that the large sinusoids lying between the neurohypophysis and pars intermedia might serve a similar function, namely, a neurovascular contact involved in the control of the adenohypophysis.

The present investigations of the pituitary vascular system of some elasmobranchs (*Scyllium canicula*, *Squalus acanthias*, *Raja batis* and *Raja radiata*) have shown the presence of a definite portal system in these species. It consists of a primary plexus on the ventral surface of the hypothalamus, portal vessels running along a kind of infundibular stem to the neuro-intermediate lobe, the sinusoids of which thus make up the secondary plexus. From the primary plexus, more or less extensive portal vessels may also open into the sinusoids of the anterior lobe, thus resembling conditions in the tetrapods.

In *Scyllium canicula*, the median hypothalamic floor between the inferior lobes is modified to a kind of median eminence. This is covered with the capillaries of the primary plexus, and the anterior lobe of the adenohypophysis attaches to its median surface. This part of the hypothalamus is very similar to the median eminence of higher vertebrates, partly because of its vascularization and contact with the adenohypophysis, but also in other details. The fibre layer under the ependyma thus contains the tractus preoptico-hypophyseus, and outside this is a zone with only scattered nerve fibres. The capillaries of the primary plexus are buried in furrows on the surface of this outer zone. The furrows are most distinct laterally; along the median part, which is in contact with the anterior lobe, the capillaries are of a simpler type.

From the primary plexus, portal vessels run backwards along the thin ventricular floor behind the inferior lobes, and enter the neuro-intermediate lobe (Fig. 1). Most of the blood enters the large sinuses between the thin 'neural lobe' and the cell cords of the pars intermedia. From these sinuses smaller vessels branch through the remainder of the neuro-intermediate lobe. A few portal vessels run from the anterior part of the primary plexus to the sinusoids of the anterior lobe.

Besides the portal system, which is median, there is also a lateral venous supply to the neuro-intermediate lobe: on either side a large vein, collecting blood from the diencephalon and anterior mesencephalon, enters the lobe[2]. Part of these veins can be seen in Fig. 1.

The arterial supply is small; there are no distinct arteries to the adenohypophysis, although small

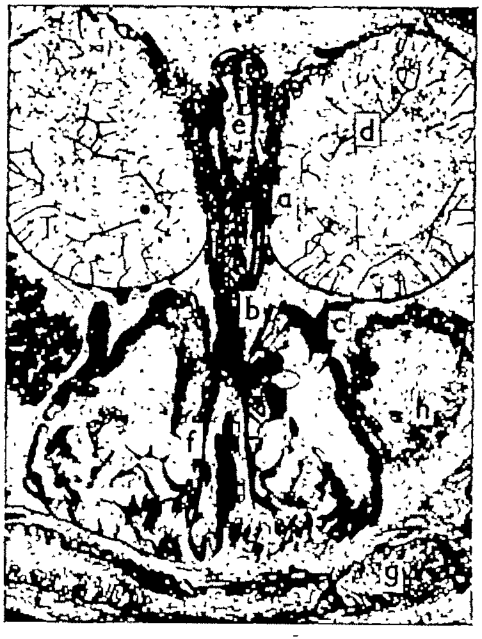

Fig. 1. *Scyllium canicula*, horizontal section through pituitary. Indian ink injection, 'Celloidin', 100*µ*. *a*, Primary plexus; *b*, portal vessels; *c*, lateral afferent vein; *d*, inferior lobe; *e*, anterior lobe; *f*, neuro-intermediate lobe; *g*, ventral lobe; *h*, saccus vasculosus

vessels reach its margins. Thus, small arteries run along the inferior lobes, close to either side of the anterior lobe, supplying mainly the primary plexus, with no observable direct branches to the anterior lobe. There are also arteries to the posterior part of the infundibulum; they probably give a small arterial contribution to the neuro-intermediate lobe and saccus vasculosus.

The gland is drained by a short venous trunk at the posterior ventral aspect of the neuro-intermediate lobe. It enters the large transversal sinus interorbitalis.

In *Squalus acanthias* the primary plexus is less distinct and most of the portal vessels enter the anterior lobe; only a small number run caudally to the neuro-intermediate lobe. Lateral afferent veins and a ventral drainage are also present in this species.

In *Raja batis* and *R. radiata* the ventricular floor behind the inferior lobes is very much expanded laterally and is covered by a dense system of parallel, longitudinal portal vessels. They enter the neuro-intermediate lobe in a manner similar to that of *Scyllium canicula*. Lateral afferent veins appear to be absent in *Raja*, but there is a large ventral vein draining the gland, running along the interhypophysial peduncle. Both *Raja* and *Squalus* have distinct arteries to the neuro-intermediate lobe.

In view of the constant occurrence of the pituitary portal system in the tetrapods, it is interesting to find a similar system also among the elasmobranchs. A noticeable difference is that in *Scyllium* and *Raja* most of the portal vessels enter the neuro-intermediate lobe, with only minor connexions with the anterior lobe. In higher vertebrates the portal vessels invariably run to the pars distalis, and appear to be the only or main vascular supply to this part of the pituitary.

The presence of a pituitary portal system and a distinct median eminence in elasmobranchs makes it necessary to modify earlier opinions on the phylogenetical derivation of the tetrapod neurohypophysis[3]. The differentiation of the neurohypophysis into a median eminence and a neural lobe may thus have taken place at an earlier stage in vertebrate evolution than previously assumed.

Sensory Innervation of the Anal Canal

Duthie and Gairns in a short communication[1] directed attention to the rich sensory innervation of the mucosa of the human anal canal.

This is a preliminary report of a further investigation of the sensory innervation of the anal mucosa and of the adjacent external (voluntary) anal sphincter.

Autopsy and operative specimens of whole human anal canals, excised with the last centimetre or so of the rectum and the attached circumanal skin, were fixed in 10 per cent formal saline. Fresh specimens of cat and rat anal canals were similarly fixed. Longitudinal serial $7\frac{1}{2}$-μ sections through the canals were either stained with Ehrlich's hæmatoxylin and eosin, or impregnated with silver according to Bodian's silver protargol method, using silver proteinate obtained from Roque's Laboratory, Paris[2]. Other blocks of material were impregnated according to the Bielschowsky method for pieces with pyridine treatment[3], and then serially sectioned at $7\frac{1}{2}$μ. Frozen 20-μ sections of the fixed rat material were impregnated by the Bielschowsky–Gros silver diamine ion technique[4].

In the human material the distribution of the encapsulated, or organized, sensory nerve endings conforms to Weddell's generalization[5] that such endings are only found in non-hairy skin.

Three kinds of encapsulated ending were found, lying either immediately beneath the stratified epithelium of the canal or deep in the connective tissue of the lamina propria.

The largest endings are approximately 900μ in size and possess an elongated lamellated capsule similar to that of Pacinian corpuscles. The nerve terminals, however, are not of the simple kind found in Pacinian corpuscles but are branched and coiled (Fig. 1). This large variety of ending is only infre-

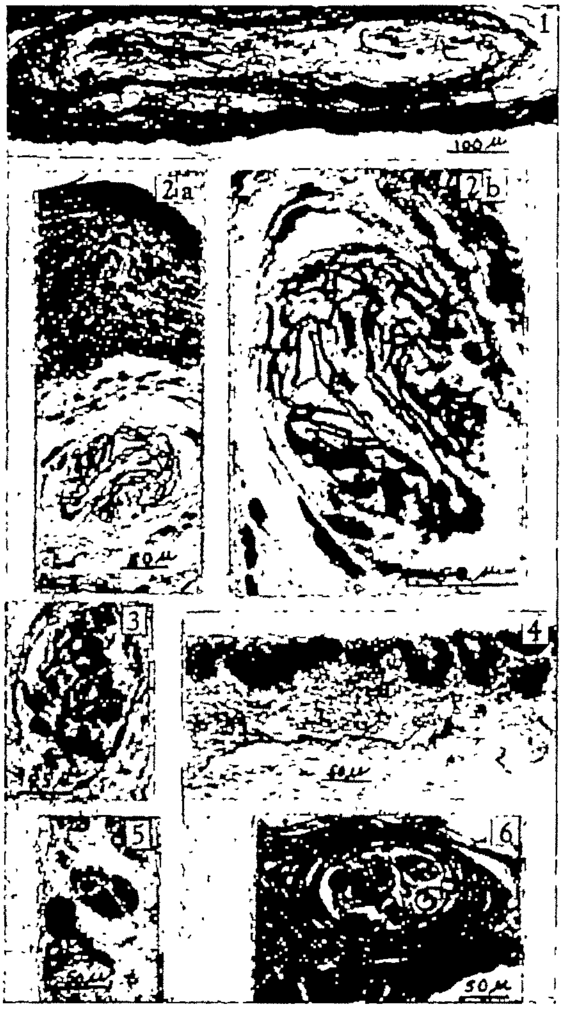

Fig. 1. Large encapsulated nerve ending. Fig. 2a. Low power showing medium-sized, organized ending lying under anal epithelium. Fig. 2b. High power of same ending showing the reticulum of sensory nerve endings. Fig. 3. Small organized ending. Fig. 4. Plexus of free nerve fibres at junction of rectal type epithelium and stratified squamous epithelium of anal canal. Fig. 5. T.S. muscle spindle from cat external sphincter. Fig. 6. T.S. muscle spindle from human external anal sphincter

quently found, usually lying close to the smooth muscle of the internal sphincter.

The most prevalent ending is globular or oval in shape, some 200μ in diameter. The nerve terminals form a branched tangled reticulum surrounded by a fairly simple capsule of connective tissue fibres and cells (Figs. 2a and b).

Fig. 3 shows the smallest kind of end-bulb, 100μ in diameter. Their nerve terminals are branched but relatively uncomplicated in their ramifications.

These encapsulated endings are most numerous in the mucosa of the upper part of the canal—six or more endings may often be observed in one section—and gradually become sparser in distribution as the anal orifice is approached.

Unencapsulated naked nerve terminals form a particularly rich subepithelial and intraepithelial plexus. In the circumanal skin typical peritricheal endings and free nerve endings were observed, but no organized endings.

No encapsulated endings were found in the rat anal mucosa, only a plexus of free nerve terminals, which was particularly obvious in the first segment of the canal (Fig. 4).

Proprioceptive endings of the muscle-spindle kind were observed in both human and cat external sphincters (Figs. 5 and 6). The correlated physiological observations in the cat have been reported elsewhere[6].

The human spindles are histologically more complicated than those found in the cat. Their connective tissue capsule is thicker and usually there are more intrafusal fibres present. Often the intrafusal fibres are arranged in two separate groups, each surrounded by its own connective tissue sheath, and both groups bound together in a common capsule. In serially sectioned cat sphincters not more than six spindles have been counted. They appear to be equally sparse in human sphincters.

It is concluded that the rich sensory innervation of the anal mucosa and the proprioceptive endings in the external sphincter provide a morphological basis for the extreme sensitivity of the anal region and must be taken into consideration in explaining the physiology of defaecation.

May I thank Prof. E. W. Walls for his directing my attention to this problem and his guidance throughout the work.

BIOLOGY

Laminated Structure of Bones from Some Marine Mammals

IN recent years much attention has been paid to methods of age determination for marine mammals, and several reliable techniques are now available. Ovarian corpora albicantia counts[1,2], baleen plate ridges[3], internal growth layers in the dentine and cementum of teeth[4], and laminations in the ear plug of baleen whales[5] are in use. Certain of these techniques have been applied with success to some terrestrial mammals, notably the method based on tooth structure[6,7]. In other species, marine and terrestrial, these methods cannot be used.

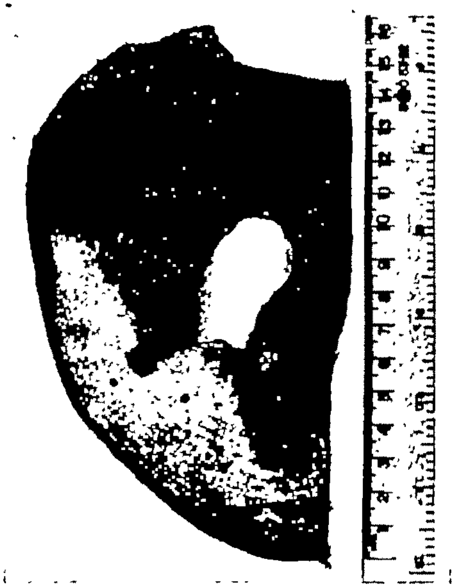

Fig. 1. Photograph of polished section of left ramus of lower jaw of an adult male sperm whale

In 1953 I described and figured the layered appearance of the dense bone of the tympanic bulla of some elephant seals, *Mirounga leonina* L.[8], but was then unaware of a paper by Chapskiy[9] in which he describes and figures such layers in the mandibles of *Phoca groenlandica* and *Odobenus rosmarus*. He showed that the number of layers is correlated in a general way with estimates of age based on other characters, and suggested that the layers are annual formations. The greatest number present in his relatively small sample of harp seals was 25. He mentions that this layered structure is found in other bones and gives reasons for preferring the mandible for routine use. It is usually the most convenient bone to collect.

I recently had occasion to examine the lower jaw of a large male sperm whale, *Physeter catodon*, caught in the Antarctic. The ventro-lateral part of the mandible is composed of compact bone, some 3–4 cm. thick in places, in contrast to the remaining spongy bone. In section it shows a number of distinct layers (Fig. 1).

These layers may be of fairly general occurrence and the purpose of this communication is to direct attention to them as a possible method of age determination. Chapskiy's important paper[9] would appear not to be generally known to biologists interested in these problems. Dr. D. E. Sergeant of the Arctic Unit, Montreal, has confirmed the layering of harp seal mandibles and found clear layers in *Phoca vitulina*, *Phocaena* and *Delphinus*. These layers will probably be useful for ageing the small delphinids, with minute teeth that may cease to grow at an early age. It may also be a possible method of ageing those baleen whales (for example, *Balaenoptera acutorostrata*) in which the ear plug has proved unsatisfactory. Game biologists may find it applicable to some terrestrial mammals in which the cementum increments are too small to use for age determination.

I am indebted to Dr. Sergeant for confirming the presence of layers in the mandibles of seal and Delphinid species. Chr. Salvesen and Co. kindly provided the sperm whale jaw and Mr. A. Madgwick took the photograph.

Dichorial One-Egg Twins in the Mouse

In a survey of the embryological evidence of one-egg twinning in man, Corner[1] has classified one-egg twins according to their time of separation, as follows:

(1) Separation of early blastomeres inside the zona pellucida. Each then develops its own blastocyst, the two becoming completely separate on dissolution of the zona, and implanting separately in the same way as two-egg twins.

(2) Duplication of the inner cell mass in a single blastocyst. The two embryos implant together; but their amnia and placentae are separate.

(3) A single inner cell mass differentiates two primitive streaks. The embryos will have a common amnion. Imperfect duplication of the primitive streaks will give all stages from Siamese twins to two-headed monsters.

The evidence for type 1 consists of two extreme sets of data. On one hand, it has been found in the rat[2] and rabbit[3] that after killing one blastomere at the two-cell stage, the other one is capable of developing into a normal embryo. The potentiality of a single blastomere to develop into an embryo does not, however, prove that *two* blastomeres confined within the same zona could both develop into embryos. One might expect considerable mechanical difficulties in the production of two blastocysts in the confined space. No one appears to have seen, among the thousands of mammalian ova examined (I have inspected hundreds of mouse eggs myself), any instance of two complete ova developing within one zona pellucida.

At the other extreme are the numerous examples of dichorial one-egg twins, which independent workers[4,5] have estimated to represent one-third of all one-egg twins.

The evidence for type 2 is more conclusive. At one end of the scale, isolated instances of blastocysts with two inner-cell masses have been recorded in sheep[6] and pig[7]. At the intermediate level Corner[1] gives examples of early human monochorial twin embryos with separate amnia, placentae and yolk sacs (though sometimes one yolk sac is shared). At the other end of the scale, the majority of full-term one-egg twins are monochorial with separate amnia.

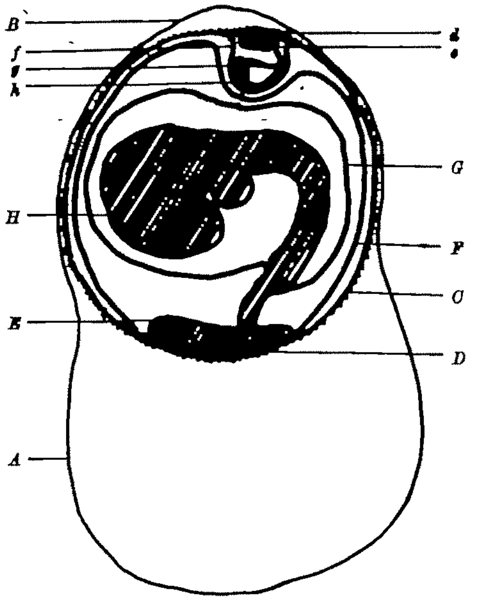

Fig. 1. Diagrammatic representation of monozygotic twin embryos in the mouse at 9½ days gestation. The uterus is not represented. *A*, Decidua basalis; *B*, decidua capsularis; *C*, trophoblast. For the other symbols, capitals stand for structures of the larger (normal) embryo and small letters for structures of the smaller (retarded) embryo. *Dd*, Ectoplacental cone; *Ee*, chorion; *Ff*, yolk sac; *Gg*, amnion; *Hh*, foetus

Type 3, illustrated by numerous human examples of twins with a common amnion, can be readily induced in Amphibia and fish. It is also the normal reproductive method in armadilloes[8], where four or eight embryos, according to the species, develop from a single egg.

I have obtained evidence of type 2 in mice, in circumstances which explain why it has not been recorded more frequently, and throws new light on the distinction between monochorial and dichorial twins. While dissecting early mouse embryos I have twice found in females, 9½ days from insemination, among numerous normal embryos, one implantation with two separate embryos within a single trophoblast (Fig. 1). The embryos were at opposite ends of the vesicle. Judging by the sheep and pig blastocysts, this is the usual arrangement. The one at the mesometrial end, attached to the decidua basalis, was much the larger of the two. In the mouse, placentation is restricted to the mesometrial line. Only the larger twin, therefore, has any future. The placenta is beginning to develop at 9½ days. The distal embryo has probably already ceased to grow and will soon be stretched out of existence by the expansion of the distended trophoblast. This makes it unlikely that one-egg twins in mice could be recognized later than 9½ days, but one would expect to have found them at earlier stages with less discrepancy in size. That I have not yet done so may be merely a matter of chance. It is just conceivable that the smaller embryo at 9½ days is secondary, developing after the larger, from trophoblast. This would account both for its small size and its absence from earlier stages.

In man, where placentation is unrestricted, both embryos such as those found in the mouse would be free to develop their own placenta and would have equal chances of survival.

Other forms of 'twinning' in the mouse are undoubtedly two-egg. It is common for two advanced (12½ days) embryos to share a common implantation site, with separate though contiguous placentæ. In litters segregating for albino these twins will often be found to differ in eye colour. I have also found two trophoblasts, one above the other at the same site. In this case they were both greatly dwarfed, presumably because each had inhibited the other.

It will be noticed from Fig. 1 that the one-egg mouse twins with a single trophoblast are dichorial, whereas most one-egg human twins are monochorial. This is because the two animals have very different types of chorion. That of the mouse is formed of extra-embryonic mesoderm, in contact with a restricted area of trophoblast, the ectoplacental cone, from which the placenta later develops. By contrast, the human chorion envelops the embryo and yolk sac. According to Corner (personal communication) it is formed from trophoblast, though it is vascularized by mesenchyme from the allantois.

The significance of dichorial one-egg twinning will obviously depend on the origin of the chorion, and since mouse chorion and human chorion do not appear to be homologous, the significance of such twins will be different in the two species. In the mouse, as in the cases described in this communication, they will signify duplicate inner cell masses from a single blastocyst (type 2). In man they will signify duplicate trophoblasts (two blastocysts from a single egg: type 1). There remains the problem of how two viable blastocysts could develop inside the same zona pellucida.

It is a pleasure to acknowledge the generous advice of Dr. George Corner of the Rockefeller Institute, New York, and of Mr. S. Bender of Chester.

Wound Healing in the New-Born Opossum (*Didelphis virginianam*)

WHILE engaged in experiments on the development of feathers in chick embryos, Saunders and Weiss[1] noted that skin wounds failed to heal when the embryos were less than 3 days old. On further investigation Weiss and Matoltsy[2,3] found, for unknown reasons, that this inability to initiate wound healing persisted until the chick embryos were at least 10 days old.

Because of the absence of an accessible experimental subject, it had not been feasible to investigate wound healing in very immature mammalian embryos. However, I have found that the new-born opossum (*Didelphis virginianam*), because of its 12-day gestation period, is an exceptionally suitable subject for elucidation of this problem in mammals. At birth the opossum is physiologically and anatomically an embryo, corresponding in development to the following embryos: 10-day chick, 12-day rat and mouse, 13-day rabbit, 28-day guinea pig and 8-week human.

Two types of skin wounds were made in opossums 1–40 days old. The first series consisted of a non-sterile incision 2–4 mm. in length and extending into the muscle. The second series were burns of the same size made by application to the skin of needles heated at 200° to 210° F. The incised wounds became grossly infected; the burns did not.

There was a 90 per cent mortality within 2 or 3 days of injury in animals less than 6 days of age with wounds induced by incision. This mortality decreased with advancing age so that the mortality was less than 2 per cent in animals of 10 days of age and older. In contrast, the mortality following a burn was less than 10 per cent in animals less than 6 days of age, and had decreased to zero in animals at least 10 days of age.

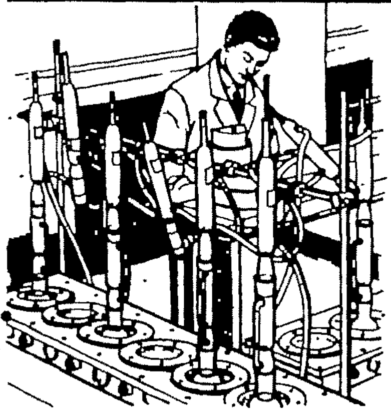
In all animals less than 6 days of age there was an almost complete lack of inflammatory reaction at the site of injury. The slight increase in cells was due to a few mitoses in local mesenchymal cells. This lack of reaction was unimportant when the wound was essentially sterile, and when there was little tissue necrosis, as occurred following the burn. In these circumstances the local mesenchymal cells were able to remove the debris and form a suitable base for spread of the epidermis over the ulcer. In contrast, when the wound became infected, as occurred after the non-sterile incisions, or if the burn was unusually deep, causing marked tissue necrosis, the injury became the site of a massive gangrenous infection resulting in death of the fœtus.

However, in all animals beginning 6 days of age the local injury elicited an intense mononuclear inflammatory response. The inflammatory cells successfully combated the local infection and within 48 hr. removed all necrotic tissue, leaving a clean base across which the epidermis bridged the defect.

The difference in reaction prior to, and subsequent to, 6 days of age was explicable by examination of the blood and hæmatopoietic tissues. Before 6 days of age there was not sufficient development of the hæmatopoietic tissues to produce significant numbers of white blood cells for the circulating blood. As a result the local mesenchyme was the only source of inflammatory cells to clear necrotic tissue and control infection. Thereafter, with progressive development of the hæmatopoietic tissues a large number of white blood cells entered the circulating blood and were able to supplement the mesenchymal cells at the site of injury as a source of inflammatory cells. The inflammatory reaction was almost as effective between 6 and 10 days of age, when the only apparent source of lymphocytes was the thymus, as after 10 days of age when lymphocytes were derived from the spleen and nodes as well as from the thymus.

These results suggest that in the opossum of less than 6 days of age wound healing ensues even in the absence of an intense inflammatory reaction provided the injured area is small and the lesion remains sterile. When the area is infected or when there is extensive local injury in animals less than 6 days of age, wound healing does not occur because the local mesenchymal cells alone are unable to control injection and clear debris. Only after 6 days of age have the hæmatopoietic tissues of the opossum developed sufficiently to provide an adequate number of circulat-

EXTRACTION AND DISTILLATION UNITS

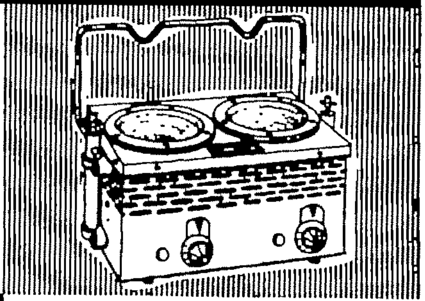


Perfect heat transfer
Accurate temperature control
Maximum safety
Minimum attention required

Extraction Units are available with three or six recesses, accepting flasks up to 1000 ml., and a controller and indicator lamp for each recess.
Non-standard units can be supplied to meet any requirement.

SERIES:— ME. MM. MQ.

Macro-Kjeldahl Units are supplied for six tests accepting flasks up to 800 ml., with a controller and indicator lamps fitted to each recess.
Units with two recesses are also available. All units are equipped with adjustable flask rests and are suitable for rack mounting.



Micro-Kjeldahl Digestion Units constructed of acid-resisting material are the most compact apparatus available. Fume tubes are fully adjustable for height and angle.

Available from all Laboratory Supply Houses.
Please request literature.

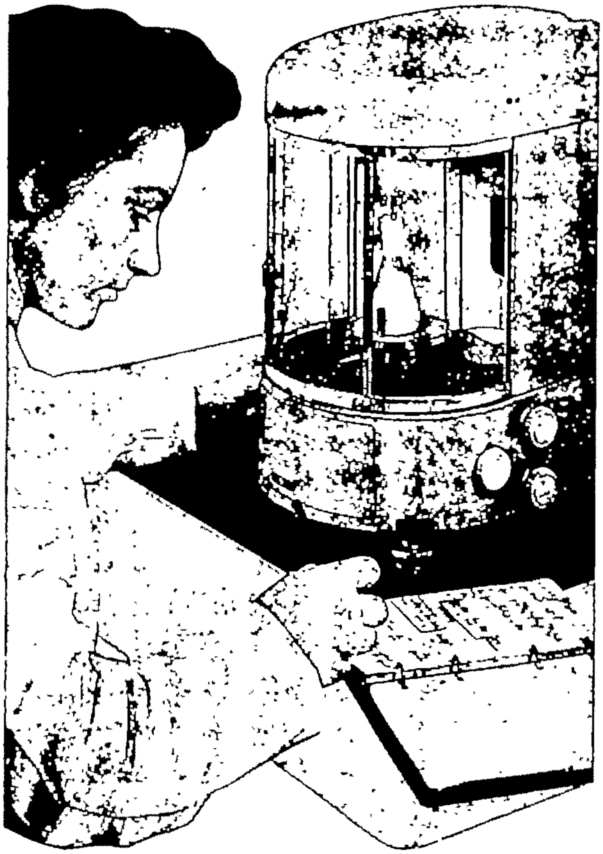
As good as it looks



The NEW Sauter

Monopan

Rapid single-pan analytical balance

The 'Monopan' is an ENTIRELY NEW instrument whose fine craftsmanship and brilliant design make it the acme of constant-load substitution balances. Controls are where you want them—low down at the sides, for comfort and convenience. The magnified projection scale, recessed to prevent reflection, is in the same field of vision as the specimen. The air damping allows very rapid reading of the screen.

All the weights—enclosed in a protective compartment underneath the pan—are manipulated mechanically. There is a taring device for containers up to 30 g. The large cylindrical weighing chamber and the special suspension of the pan, obviating swing, all help to make this new balance a joy to use. Its capacity is 200 g and it can be read easily to 1/20 mg—0·00005 g. We shall be glad to send you full details.

ing leucocytes to serve as a source of inflammatory cells. It thus seems probable that the leucocytes of the circulating blood and not the local mesenchymal cells are the major source of the inflammatory cells needed for wound healing in the embryo-like new-born opossum.

I thank the Texas Game and Fish Commission for obtaining the animals and Braniff Air Lines for flying the animals from Waco, Texas, to Denver, Colorado.

Supported by a grant from the U.S. Public Health Service.

Development of the Gonads in Parasitic and Non-Parasitic Lampreys

In relation to the origin of the non-parasitic brook lampreys the view now generally accepted is that these forms have arisen from closely related parasitic species by virtue of a precocious development of the gonads[1-3]. As a result, sexual maturity is attained so soon after metamorphosis that the migratory, parasitic phase has been eliminated from the life-cycle. The recent discovery of neotenous female ammocoetes of the Italian brook lamprey, *L. zanandreai* Vladykov[4], tends to support the view that brook lampreys show an inherent tendency towards paedomorphosis.

Through the co-operation of Dr. V. C. Applegate, of the U.S. Department of the Interior, Fish and Wildlife Service, it has been possible to examine the condition of the gonads in ammocoetes of the parasitic sea lamprey of the Great Lakes Basin, *P. marinus*, and to compare the pattern of gonad development in this species with that of the brook lamprey, *L. planeri*.

Length-frequency curves for 847 ammocoetes of *P. marinus* collected in the Ocqueoc River, Michigan, in September 1957, suggest the presence of six age classes with frequency maxima at about 25, 55, 80, 105, 124 and 140 mm. Metamorphosing specimens were found in the size-range 123–170 mm. with a frequency peak at about 145 mm. Since the 25-mm. group represents the young of the year, it is thought that the duration of the larval period is similar to that of the brook lamprey[5], that is, about five years.

To compare the size of the gonad in the two species transverse sections were cut through the mesonephric region and either photographed or traced with the camera lucida. The area of the gonad was then measured planimetrically and expressed as

$$\frac{\sqrt{\text{gonad area in mm.}^2}}{\text{total length mm.}} \times 100$$

For the first year of larval life (up to about 30 mm.), the gonad of *L. planeri* is in the proliferative phase during which the small number of germ cells present at hatching undergo successive divisions to produce follicles of undifferentiated gonia. By the early spring of the second year (35–40 mm.) some gonads already contain oocytes in the earlier stages of cytoplasmic growth. In the definitive ovary, growth is now rapid, and the gonad soon consists almost entirely of auxocytes. However, in a small proportion of ammocoetes, the gonad remains small with follicles of gonia only, while others contain, in addition to such follicles, a smaller number of oocytes. Future testes are recognizable at this stage only by their small size, relatively fewer auxocytes, and the presence of undifferentiated gonial follicles. By the summer or autumn of the second year, at lengths of about 50–60 mm., differentiation of the gonads is almost completed but the testes show little further growth between this period and metamorphosis.

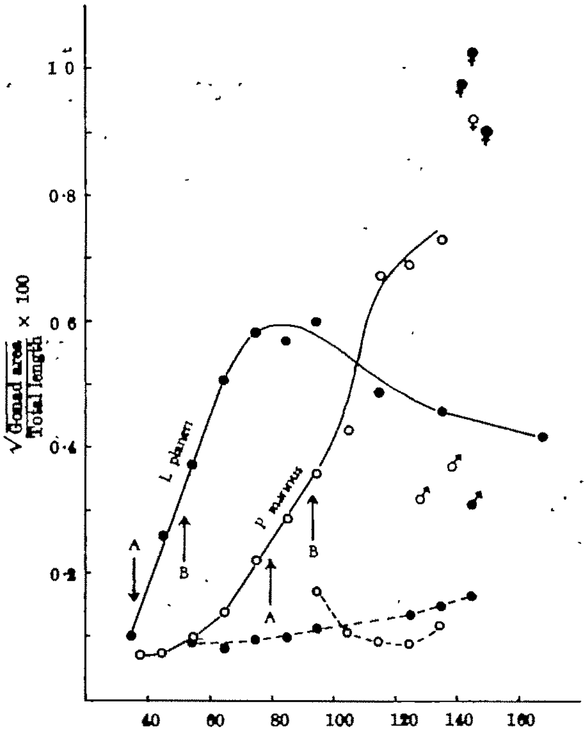

Fig. 1. Relative growth of gonads in ammocoetes of *P. marinus* and *L. planeri*. Continuous lines, ovaries and indeterminate gonads; broken lines, testes; ♀, metamorphosing females; ♂, metamorphosing males of *P. marinus*. The arrows at *A* and *B* indicate respectively the appearance of auxocytes and the onset of sex differentiation

The rapid initial growth of the oocytes is reflected in the increase in size of the gonad between 35 and 75 mm. total length (Fig. 1), beyond which the relative size of the ovary actually diminishes. There is, however, a final phase of growth, not represented in the graph, between metamorphosis and full sexual maturity, during which the diameter of the oocyte is increased from about 0·12 mm. in the largest ammocoetes to 1·0 mm. at the time of spawning.

Initially the gonads of *marinus* ammocoetes are smaller than those of *planeri* and grow more slowly up to a length of about 100 mm. Thus, in a 100-mm. sea lamprey ammocoete the gonad is no larger than that of a brook lamprey at 55 mm. and, up to lengths of 70–80 mm., it still consists of undifferentiated germ cell follicles. This extension of the period of proliferation must, of course, be associated with the vastly greater number of oocytes (or spermatocytes) produced by the sea lamprey. Oocytes in the first growth-phase occurred in the majority of animals at 80–90 mm.; but it was not possible in all cases to distinguish the definitive ovary and testis at lengths below 90–100 mm. Growth of the ovary appears to be most marked between 105 and 115 mm., and in animals above this length the gonad is relatively larger than in the corresponding brook lamprey ammocoetes. This increased size is due to the larger number of oocytes; a single transverse section often containing as many as 200 oocytes compared with an average of about 30 in the brook lamprey, while the oocytes themselves are smaller than those of *planeri* (mean diameter in the largest ammocoetes 0·3–0·4 mm. compared with 0·12 mm.). Judging from the size of the gonad in metamorphosing animals, a marked acceleration of growth must occur in both ovary and testis at this time.

Although the duration of the larval period and the linear growth-rate appear to be similar in the two species there are thus very marked differences in gonad development, both sex differentiation and oocyte growth occurring at a much earlier stage in *planeri* ammocoetes. In considering the relevance of these findings to the question of speciation in lampreys it must, however, be recognized that, except for its earlier differentiation in the brook lamprey, there are no obvious indications that the testes of these animals are in a more advanced state of development and it may perhaps be significant that all the cases of neoteny reported by Zanandrea[4] occurred in female ammocoetes.

An Acid-tolerant and Non-sporulating Yeast from Passion Fruit Juice

DURING the course of studies in the preservation of passion fruit juice (*Passiflora edulis*, Sims.)[1,2], a survey of literature revealed little published information on the nature of spoilage organisms present in the juice.

Passion fruit juice normally has 14·4–21·9 °Brix, 2·4–4·8 per cent acidity (as anhydrous citric acid), 2·60–3·22 *p*H, 3·6–8·3 per cent reducing sugars and 7·4–13·3 per cent total sugars (as invert)[3]. The juice, though acidic, is fairly rich in sugars and is easily fermentable[1]. A fermenting sample of the juice, when examined microscopically, revealed the presence of yeast cells only. No bacteria were noted.

The spoilage organisms were isolated by plating them out on potato–dextrose–agar[4] and transferring the well-defined colonies to slants of the same medium. Taxonomic studies[4,5] revealed the presence of two strains of yeast, one of which was identified as *Candida krusei*[6]. The summary of morphological and physiological studies on the other organism (*Passiflora* strain) is given below.

Cells small, oval (1·8–4·5) × (1·8–8·8) μ; no formation of pseudomycelium; a sediment after a week and a ring after a month in liquid media; no sporulation on carrot, Gorodkowa agar, potato malt-extract agar, etc.

Only glucose is fermented and assimilated. The following compounds are not assimilated by this *Passiflora* strain: galactose, sucrose, maltose, lactose, L-sorbose, cellobiose, trehalose, melibiose, raffinose, melezitose, D-xylose, L-arabinose, D-arabinose, D-ribose, rhamnose, erythritol, adonitol, dulcitol, mannitol, sorbitol and methyl glycoside, salicin, lactic acid, succinic acid and citric acid. Ethanol may be weakly assimilated. Nitrate is not used, and arbutin is not split.

The *Passiflora* strain resembles *Torulopsis glabrata* (Anderson) Lodder and de Vries, but differs from this species in that the latter ferments trehalose.

Comparing the strain to sporogenous species, it bears resemblance, in fermenting dextrose only, to: *Sacch. bisporus* (Naganishi) Lodder and van Rij, *Sacch. mellis* (Fabian and Quinet) Lodder and van Rij, *Pichia pastori* (Guilliermond) Phaff and *Sacch. delphensis* van der Walt and Tscheuschner[7].

The cells of *Sacch. mellis* and *Sacch. bisporus* are somewhat bigger than those of the *Passiflora* strain, though the difference with *Sacch. bisporus* is not great. However, *Sacch. bisporus*, *Sacch. mellis* and also *Pichia pastori* can assimilate mannitol and sorbitol, which compounds are not used by the *Passiflora* strain.

On the other hand, the assimilation tests of the *Passiflora* strain and *Sacch. delphensis* show much correspondence, differing only by a weak assimilation of succinic acid found in the latter. For growth, both strains need the addition of vitamins to the medium. They grow at 37° C. Also in the morphological properties, there is similarity, apart from the formation of kidney-shaped spores after isogamous conjugation in *Sacch. delphensis*. This species has been isolated from the sugary efflorescence on dried figs (Kregar-van Rij, N. J. W., private communication).

Based on the above observations, we are inclined to consider the *Passiflora* strain provisionally as a non-sporulating strain of *Sacch. delphensis*.

We are indebted to Mrs. N. J. W. Kregar-van Rij, Centraalbureau voor Schimmelcultures, Yeast Division, Julianalaan 67A, Delft, Holland, for help rendered in the identification of the yeast, to Dr. Girdhari Lal, assistant director, and Dr. V. Subrahmanyan, director of this Institute, for their keen interest in this investigation, and to Shree S. A. Jaleel, for assistance in the work.

Ensete berryi: Revised Name for *Musa enseteformis* Berry

WORKING on some petrified plants from the Deccan Intertrappean Series of India, I have found certain well-preserved specimens of fossil bananas to be described in detail elsewhere. Looking into the geological history of the genus *Musa*, I find that *Musa enseteformis* Berry[1] is the only definite palæobotanical record of the old genus *Musa* L. This species was based on some carbonized seeds recovered from the coal beds of Cerros de Guadalupe and Montserrate in the eastern border of the Sabana of Bogota, Colombia. The exact horizon from which these seeds were obtained was not known; but Berry considered them to be of Oligocene age.

Recently, Cheesman[2] has split the old genus *Musa* into *Ensete* Horan. and *Musa* L. As evident from their structure and as suggested by the specific name *ensetaformis*, the seeds described by Berry[1] are clearly referable to the newly revived genus *Ensete*. In the light of these facts, the name of *Musa ensetaformis* should be revised. Usually in such cases the generic name is changed and the specific name is combined with it. But to avoid the repetition of the generic name in the specific epithet, I propose a new combination *Ensete berryi*, with the specific name in honour of the original author.

My sincere thanks are due to Dr. R. N. Lakhandal for going through this communication critically.

Unproductivity in the Colchicine-Induced Tetraploids of *Annona squamosa* L.

Only two out of a large number of colchicine-treated *Annona squamosa* plants reported earlier[1] proved pure tetraploid on chromosome examination. The one suspected to be tetraploid on morphological grounds and reported in that paper to have borne fruits earlier than the control was found to be diploid. The two pure tetraploids have been under observation since 1951 but until now neither of them has borne any fruit although they come to blossom every year. The flowers on both these plants wither away on the day following their opening.

Selfing did not help in the fruit formation nor pollination by the pollen from the diploid parent. Application of hormone on the flower stalk did not also prevent the shedding of flowers. The addition of nitrogen, phosphorus and potassium in various combinations, and the root exposure did not improve the situation.

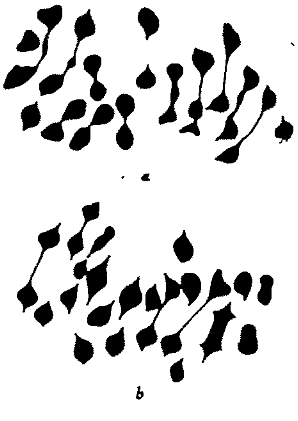

Fig. 1. (*a*) and (*b*), Side view of metaphase I showing 1III, 10II and 5I and 1III, 7II and 11I respectively. × 1,200

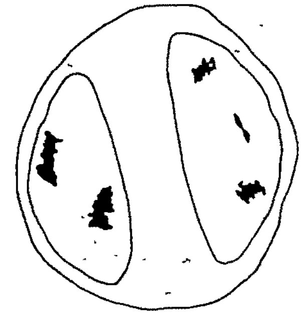

Fig. 2. Side view of anaphase II. Note the lagging chromosome in the right-hand cell. ×600

In order to understand the causes of unproductivity meiotic studies were made from pollen mother-cells in aceto-carmine. Early stages of prophase could not be studied as the chromosomes took feeble stain. None of the diakinetic nuclei studied showed any quadrivalents. Trivalents, bivalents and univalents were only found, the maximum number of trivalents and univalents observed in any pollen mother-cell being 3 and 7 respectively. The side view of metaphase I was studied from 30 pollen mother-cells. Various associations of trivalents, bivalents and univalents were seen, the number of trivalents ranging mostly from one to two and that of univalents from three to as many as eleven. Figs. 1*a* and *b* show one trivalent and five and eleven univalents respectively. The presence of trivalents and a large number of univalents led to a more unequal segregation of the chromosomes at anaphase I than what would have been expected if the quadrivalents were present in place of trivalents and univalents. Lagging chromosomes were also seen in anaphase I as well as in anaphase II (Fig. 2).

These meiotic irregularities resulted in the formation of sporads containing from 1–5 cells (Fig. 3). Some of the sporads formed a linear tetrad instead of the usual isobilateral type. A count of the unstainable pollen grains showed that these were present to the extent of about 80 per cent. Megasporogenesis has not been studied, but it may be presumed that this

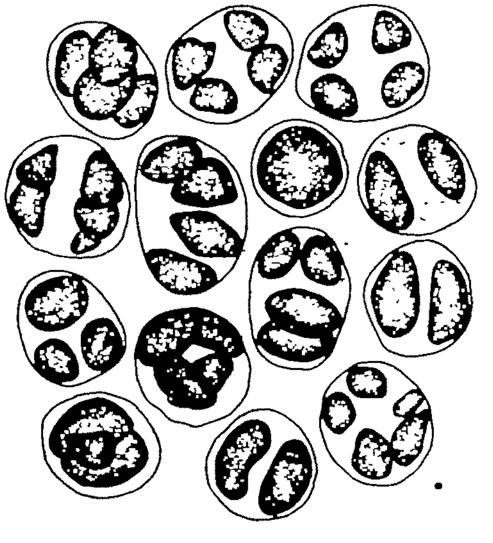

Fig. 3. One- to five-cell sporads in the *c*-tetraploid *Annona squamosa* L. × 275

kind of irregularity in meiosis may lead to a high percentage of aborted megaspores. Chances are therefore very remote for a normally developed megaspore to be fertilized by a balanced male gamete. Thus the failure of fruit formation may be primarily due to irregular meiosis which results in the abortion of as much as 80 per cent pollen grains and possibly the same percentage of megaspores.

The artificial induction of polyploidy always brings about sterility in the induced plants but the report of complete sterility in the colchicine-induced tetraploids is rare. The complete unproductivity of the c-tetraploid *A. squamosa* is quite contrary to the expectation as the experiments on induced polyploids in the past have shown that cross-pollinated diploid plants with a low number of small sized chromosomes (to which class *A. squamosa* belongs) respond favourably to the action of chromosome doubling[2].

I gratefully acknowledge the financial assistance received from the Food and Agriculture Council of Pakistan in carrying out this piece of research work. My thanks are also due to Dr. Majeed Ahmad, University of Dacca, for giving me facilities to work in the laboratory and the botanic garden where the two tetraploid plants are growing.

Intracellular Configuration and Dedifferentiation in *Splachnum ampullaceum* (L.) Hedw.

IN studies on protonematal regeneration from gametophore leaves of *Splachnum ampullaceum* (L.) Hedw., it was found that isolation and not wounding is the most important factor in the realization of regenerative potentialities[1]. The removal of correlative inhibition by means of isolation initiates cellular dedifferentiation, followed generally by cellular redifferentiation. The present work was undertaken in order to investigate certain aspects of cellular dedifferentiation.

The plant material was grown under sterile conditions on Beijerinck's inorganic medium solidified with 1 per cent agar and was kept under continuous white light provided by fluorescent lamps. Cells of detached half-leaves were compared with those of half-leaves attached to a stem segment. Protonematal regeneration occurs readily from cells of the former while it does not occur from those of the latter[1].

Table 1 shows a comparison of nuclear size and chloroplast size and number between cells of attached and detached half-leaves. Measurements were made at selected time-intervals following the surgical treatment. Cells in the immediate neighbourhood of the wound surface are not included. These results show that nuclear size increases considerably in cells of the detached half-leaves during the first 24 hr. after isolation while remaining approximately constant in cells of the attached half-leaves. Similarly, chloroplast size decreases slightly and chloroplast number increases greatly in cells of detached half-leaves while remaining approximately unchanged in attached half-leaves. Since attached and detached half-leaves have about the same wound surface present, the recorded changes in the nuclei and chloroplasts are due not to wounding but to leaf isolation. Isolation, therefore, results apparently in greatly increased synthetic activity of the cells. Preliminary comparisons between cells of older detached half-leaves and those of younger ones indicate that these changes occur at considerably slower rates in the cells of the older leaf.

Table 1. NUCLEAR SIZE, CHLOROPLAST SIZE AND NUMBER IN CELLS OF ATTACHED AND DETACHED HALF-LEAVES

Hr. after treatment	Diameter of nucleus (mm. × 10^{-3})		Diameter of chloroplast (mm. × 10^{-3})		No. of chloroplasts	
	Attached	Detached	Attached	Detached	Attached	Detached
0	6·29	6·14	6·03	6·20	73	65
10	6·14	6·52	6·08	6·05	69	66
24	6·68	7·50	6·13	5·49	75	99
48	6·29	—	6·06	—	75	—
72	6·74	—	6·11	—	79	—

Fundamental changes in the relative position of the various cellular components in cells of detached half-leaves precluded observations on nuclear size and chloroplast size and number beyond 24 hr. after isolation. In a mature leaf cell the cytoplasm is limited to a thin layer along the cell wall surrounding a large vacuole. Under the present light conditions the chloroplasts are in peristrophe. The nucleus is in a peripheral position. While this pattern is maintained in cells of the attached half-leaf, there is a pronounced change in cells of the detached leaf. Within a few hours after isolation intravacuolar strand formation is observed, a primary cytoplasmic strand being formed first connecting the cytoplasm around the nucleus with the cytoplasm at the side opposite the nucleus across the vacuole (Fig. 1). Primary cytoplasmic strand formation is followed by the formation of other strands reaching a maximum

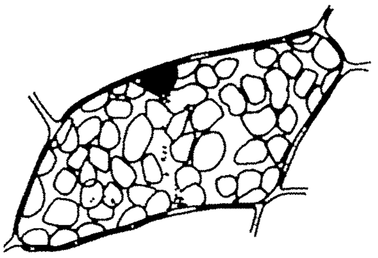

Fig. 1. Surface view of leaf cell 6 hr. after leaf isolation

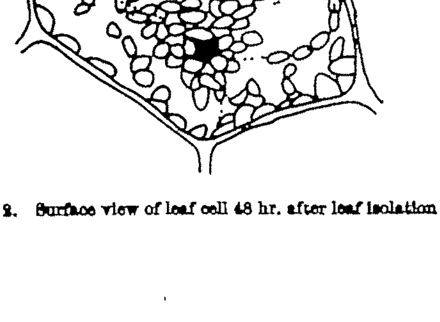

Fig. 2. Surface view of leaf cell 48 hr. after leaf isolation

between 24 and 48 hr. after isolation of the leaf. Intravacuolar strand formation is followed by the movement of the nucleus and the chloroplasts from a peripheral to a more central position in the cell. Hence the cytoplasmic strands facilitate a clustering of cytoplasm and chloroplasts around the nucleus, resulting in a typical systrophe or cluster formation (Fig. 2). Ultimately one cytoplasmic strand becomes the most prominent one, and cell wall formation is initiated along this strand. This strand represents, therefore, the phragmosome[1]. The remaining strands disappear gradually.

Strand formation leading to systrophe is, therefore, an important event in cellular dedifferentiation and results here simply from isolation. These results are in agreement with Heitz's[3] important observations on regeneration and his suggestion that wounding cannot be the important factor in the initiation of events leading to cellular regeneration. Sinnott and Bloch[2] have described cell division in vacuolate plant cells in normal plant development. Their illustrations show strand formation resulting in a more central position of the nucleus and cytoplasmic cluster formation around the nucleus. Thus in normal plant development enlarging yet still actively dividing cells undergo dedifferentiation accompanied by cytoplasmic cluster formation before each division. Hence changes in intracellular configuration which occur during dedifferentiation and which in the present instance are the result of isolation appear also to be a characteristic of normal plant development.

ENTOMOLOGY

Prevention and Artificial Induction of the Imaginal Diapause in *Coccinella* *7-punctata* L.

By field observations, dissections and analyses of field samples it was discovered that the female diapause in *Coccinella 7-punctata* L. (Col.: Coccinellidae) is connected with a gonotrophic dissociation, which is not the case in male individuals. After the induction of diapause the adults of both sexes accumulate reserves (fats and glycogen); afterwards they stop feeding and migrate towards the winter quarters. During this prehibernation accumulative feeding-period, the females remain sexually immature. On the other hand, for males the maturation of gonads is not such a strain on energy reserves; both diapausing and active males rapidly reach maturity and only stop tissue activity in testicular follicles immediately before hibernation. At this period they have already accumulated sperm reserves in the seminal vesicles and encysted sperms in the testicular follicles. Already before hibernation they fertilize a part of the females, hibernating afterwards with sperm reserves in the spermatheca. In the spring the males renew their sexual activity long before the females. They fertilize females in the hibernating quarters. The ovaria mature later—only after feeding on the essential aphid food. During hibernation the fat reserves in both sexes are reduced to a half; the glycogen in males to one-fifth, in females to one-third.

A mixed population, consisting of monovoltine insects with the obligate diapause and of polyvoltine insects with the facultative diapause, obviously lives in Central Europe.

In order to reveal the mode of action of factors inducing the diapause we tried to prevent this phenomenon experimentally and, on the other hand, to induce it artificially.

By breeding the Coccinellidae under optimal conditions of a continual excess of food (aphid *Pergandeida medicaginis* Koch), long photoperiod (16–18 hr.) and a higher slightly alternating temperature (mean 25° C.; 22–28° C.) we succeeded in gradually preventing the diapause[1]. It is obvious that a gradual selective elimination of the monovoltine insects resulted. It is then possible to breed the ladybirds continuously. When any departure from the optimal culture conditions has arisen (especially from excess of food in cages with many individuals) a certain amount of diapausing ladybirds also developed in the next generations. This situation is very similar to that in *Leptinotarsa 10-lineata* Say. The possibility of interpreting this feature in the same way in both these insects arises from the results by De Wilde and Stegwee[2]: they found a marked decrease of the number of diapausing females in the cultures of single pairs of *L. 10-lineata*.

Experiments with polyvoltine Coccinellidae from artificial cultures showed that there is a correlation between the photoperiod and temperature in the induction of imaginal diapause, the photoperiod being the more significant factor[3]. The long photoperiod (16 or 19 hr.) appears to prevent the diapause even at a relatively low temperature (18° C.). The short photoperiod (8 or 12 hr.) induces the diapause. In a short photoperiod the induction of diapause is stimulated in addition by a low temperature; but inhibited by a high one.

The character of the artificially induced diapause was studied by comparative dissection and analysis. Dissection did not reveal any differences in the fat body and ovaria. Analysis showed that females with artificially induced diapause had the same glycogen reserve, and that the fat reserve was only one-fifth lower than in the naturally diapausing females. On the other hand, in experimental active females the fats were less than a half and glycogen just half the amount in the experimental diapausing females. On the basis of these results, the artificially induced diapause can be considered equivalent to the natural diapause.

Immunity of Aphids to Insect Parasites

A STUDY has been made of the susceptibility to, or immunity from, parasitism which certain aphis exhibit towards the insect *Monoctonus paludum* Marshall (Hymenoptera, Braconidae). Starý[1], in a recent revision of the European species of *Monoctonus*, identifies *M. paludum* with *M. crepidis* Haliday, which has been recorded from various aphid hosts on plants related to lettuce. The present account is concerned only with the association between the parasite and aphids which occur on lettuce, and it has been found that although the parasite will readily oviposit into the five species of lettuce aphids which have been studied, successful development of the parasite can only occur in one of these species.

During oviposition the female parasite lays a single egg, with precision, into the fused thoracic ganglia of each aphid, and it has been shown[2] that the parasite will readily attack the following species of aphids occurring on lettuce: *Nasonovia ribis-nigri* (Mosley), *Macrosiphum euphorbiae* (Thos.), *Myzus persicae* (Sulz.), *Aulacorthum solani* (Kalt.), *Aulacorthum circumflexum* (Buckton).

However, of these five species of aphids only *N. ribis-nigri* supports successful development of the parasite's eggs and, in order to determine the reasons for failure of parasite development in the other species, sections and dissections of these aphids have been carried out at various time-intervals after attack.

A full report of this work will be given in a subsequent paper. The interesting facts which emerge at the present time are that segmentation of the parasite egg begins normally in all the aphids studied but that, in the species *Macrosiphum euphorbiae*, *Myzus persicae* and *Aulacorthum solani*, degenerative changes then occur which result in the shrinkage of the parasite tissues and their subsequent disappearance at a later stage.

In the species *Aulacorthum circumflexum*, however, a different form of immunity reaction occurs. This reaction is contrary to the contention of Flanders[3], who stated that cellular or phagocytic immunity does not occur in aphids because the number of blood cells is relatively few, for, in this species of aphid, the development of the parasite is arrested by the secretion, around it, of a capsule formed by certain of the host's blood cells. This capsule differs from the relatively thick capsules described by Salt[4-6] in a variety of different insect species as a result of artificial injection of eggs and larvæ of the parasite *Nemeritis* (Hym. Ichneumonidae) but resembles more the thin, brown capsules described by Schneider[7] in the syrphid *Epistrophe balteata* as a defence against the ichneumon *Diplazon*. The appearance of the capsule in *A. circumflexum* during its process of formation is shown in Fig. 1.

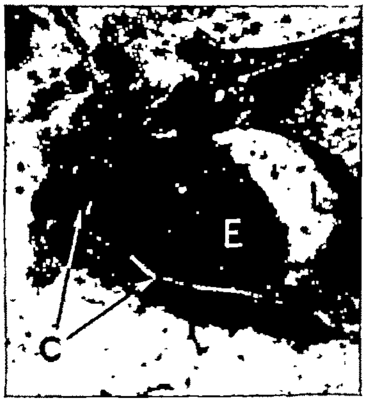

Fig. 1. Section through part of the thoracic nerve ganglia of *Aulacorthum circumflexum*, 24 hr. after attack by *Monoctonus paludum*. The capsule (*C*) is beginning to form around the parasite embryo (*E*), which lies in a space in the nervous tissue of the host

Function of the Corpus Allatum in 'Dauer-pupa' of the Silkworm, *Bombyx mori*

RECENTLY it was reported[1] than when the corpora allata in the Eri silkworm pupæ were transplanted into artificially diapausing pupæ which were obtained by removing their brains at early pupal time, the diapausing pupæ were induced to emerge in 25 days after the implantation. On the contrary, when the corpora allata derived from the fourth, the fifth instar larvæ or moths of the same insect were transplanted into the artificially diapausing pupæ of the Eri silkworm, most operated animals entered the second pupal instar several weeks after transplantation. The same results were obtained in an experiment on the Cecropia silkworm[2]. When the corpora allata from the Cecropia moths were transplanted into the diapausing pupæ of *Hyalophora cecropia*, the operated insects became the second pupæ.

My co-worker and I have shown[3] that in *Bombyx mori* each corpus allatum removed from the fourth, the fifth instar larvæ, pupæ and moths respectively had a function which brought about imaginal development probably through the prothoracic gland in 'Dauer-pupæ'.

It is not known, however, whether the corpus allatum in 'Dauer-pupa' of the silkworm, *Bombyx mori*, has the same function in relation to imaginal differentiation as corpus allatum in normal larva, pupa and moth.

In this communication a function of the corpus allatum in the 'Dauer-pupa' of the silkworm, *Bombyx mori*, is revealed.

So-called 'Dauer-pupæ' of an F_1 hybrid between two varieties, *J*.122 and *C*.115, which had been obtained by extirpating the brain immediately after pupation and did not show any sign of imaginal differentiation for 45 days at 25° C. after pupation, were used as recipients of the corpora allata which were removed from 'Dauer-pupæ' of 45 days old as grafts.

As shown in Table 1, of 20 'Dauer-pupæ' grafted with 3 pairs of corpora allata derived from the 'Dauer-pupæ', 11 recipients became moths 17–24 days after operation, but the other 4 animals survived

Table 1. Effect of Implantation of Corpora Allata* of 'Dauer-pupa' on the Induction of Imaginal Development in 'Dauer-pupa'

No. of 'Dauer-pupa'† used as recipient	No. of individuals died	No. of moths emerged (days from implantation to emergence)	No. of undeveloped individuals‡
20	5	3 (17), 3 (18), 4 (19), 1 (24)	4

* Three pairs of corpora allata were implanted into each recipient pupa.

† So-called 'Dauer-pupae' which were obtained by depriving the pupae of their brains immediately after pupation, and kept at 25° C.

‡ The result obtained in 30 days at 25° C. after implantation of corpora allata.

having sustained the pupal form until 30 days after implantation.

Twenty control animals not implanted did not show any sign of imaginal differentiation under the same condition as the experimental animals for 100 days after pupation.

Accordingly, from this experiment, it is concluded that the corpus allatum in 'Dauer-pupa' has the same function as silkworm larva, pupa and moth.

In spite of the fact that each 'Dauer-pupa' had a pair of native corpora allata, they did not show any sign of imaginal differentiation for a comparatively long time. The reason why this phenomenon occurred is to be clarified.

BACTERIOLOGY

Recovery in the Presence of Chloramphenicol of *Escherichia coli* B(H) Irradiated with Ultra-violet Light

It has been observed in several instances that protein synthesis is involved in the effects produced in micro-organisms by irradiation with ultra-violet light, as has been shown by changes during post-irradiation incubation. Witkin[1] and Doudney and Haas[2] obtained results which suggested the importance of protein synthesis in the induction of mutation by *Salmonella typhimurium* and *Escherichia coli* respectively, Gillies and Alper[3] in the recovery of *Escherichia coli* B and Harold and Ziporin[4] in the synthesis of deoxyribonucleic acid in *Escherichia coli* B. We have found that the synthesis of ribonucleic acid in *Escherichia coli* B(H)—a strain obtained from Prof. Itaru Watanabe, Virus Laboratory, University of Kyoto, which has a specific property in bacteriophage infection[5]—is completely dependent on the protein synthesis which occurs during the first 30 min. of post-irradiation incubation[6]. We have therefore investigated the biological and chemical nature of protein produced in this way, and some of the results are described here.

When cells of *Escherichia coli* B(H) irradiated with ultra-violet light (surviving fraction 0·1 per cent) were incubated in *tris*-glucose medium[7] at 37° C., the number of colony-forming cells increased about tenfold after 1 hr. Chloramphenicol (40 µgm. per ml.), which was added to the culture at the beginning of incubation, suppressed this increase considerably for at least 2 hr. When, however, the drug was added after incubation for 30 min., recovery was not suppressed but rather stimulated as compared to the control culture which contained no chloramphenicol (Fig. 1).

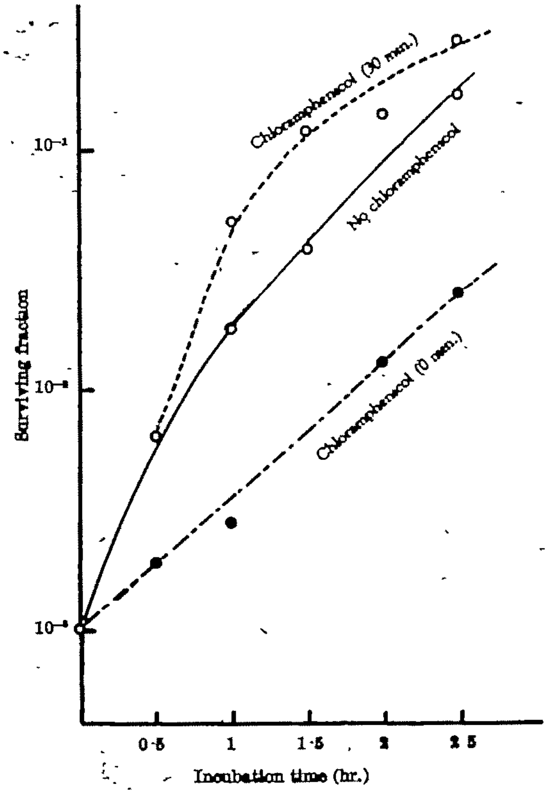

Fig. 1. Effects of chloramphenicol on the recovery of *Escherichia coli* B(H) irradiated with ultra-violet light. The numbers in parentheses show the time of addition of the drug

If protein synthesis during the first 30 min. of incubation is essential for the recovery of the irradiated cells, as suggested by the above experiment, the protein which has already been synthesized as a result of the first irradiation and the following incubation might also be useful during recovery after a second irradiation.

Cells of *Escherichia coli* B(H) in logarithmic growth phase were harvested and irradiated with ultra-violet light; this resulted in a decrease in the number of survivors to 0·2 per cent. These cells were incubated in *tris*-glucose medium for 60 min. at 37° C. in a reciprocal shaker. During incubation the number of survivors increased about tenfold. These cells were subjected to a second irradiation with the same dose as the first one. The decrease in the number of survivors was a little more than in the first irradiation. After this, the cells were incubated in *tris*-glucose medium with and without the addition of chloramphenicol (40 µgm. per ml.). At time intervals colony counts were made by plating on to nutrient agar plates. The results are shown in Fig. 2.

In contrast to the results shown in Fig. 1, when chloramphenicol is added at time zero, it does not suppress recovery but rather stimulates it. The effect is nearly the same as when the drug is added at 30 min. after the first irradiation (Fig. 1). These

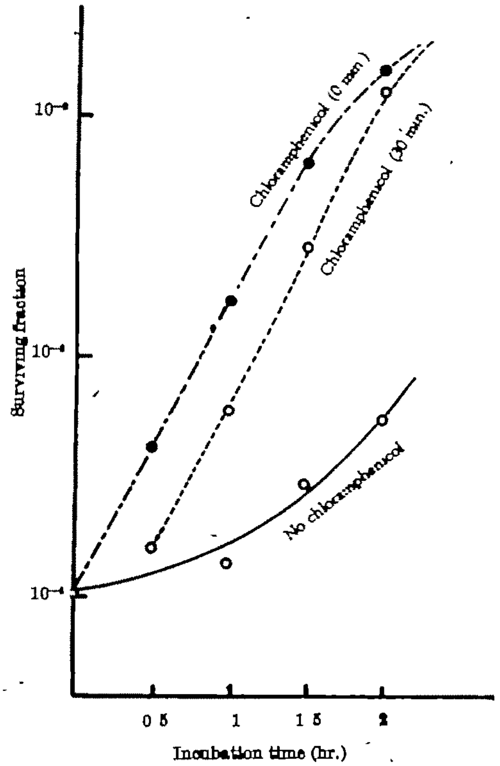

Fig. 2. Effects of chloramphenicol on the recovery of *Escherichia coli* B(H) after second irradiation with ultra-violet light. The numbers in parentheses show the time of addition of the drug

results can be explained if it is supposed that protein synthesis is not necessary for the recovery phenomenon after the second irradiation, because the essential protein has already been synthesized in the cells as a result of the first irradiation and the following incubation. That the observed increase in survival during the post-irradiation incubation is not due to cell division but to 'recovery' is indicated by the fact that it occurs even under severe conditions such as nitrogen or phosphorus starvation, addition of antibiotics, etc. Further, the rate and extent of recovery are usually very high; for example, about one hundredfold recovery is observed during incubation for 2 hr. The one-generation time for non-irradiated *E. coli* B(H) in *tris*-glucose medium is about 60 min.

Further work on the nature of this protein is now in progress in our laboratory.

Host-Range of *Lactobacillus* Bacteriophages

IN 1955, Kiuru and Tybeck[1] isolated a phage specific for 1 strain of *Lactobacillus lactis* and a phage working on 2 strains of *L. helveticus*. These phages were isolated from cultures used in the manufacture of Swiss cheese. In 1958, Meyers *et al.*[2] reported the isolation from saliva of phages active on 7 *Lactobacillus* species. The host-range of these phages was not indicated.

Using the enrichment technique of Adams[3], we have isolated 14 *Lactobacillus* phages. Media employed have been described by Briggs[4]; cultures were incubated at 37° C. in an atmosphere of carbon dioxide. Mixtures of sewage and groups of 12 *Lactobacilli* were used in different experiments. Aliquots were centrifuged daily for 10 days and the supernatant spotted on cultures of the 12 organisms. Lytic activity was never demonstrated before the second and usually only after the sixth day of incubation. The possibility that the phages originated from lysogenic members of the bacilli used for enrichment and not from sewage is being investigated. Phage was purified by picking off a single plaque into a young broth culture of the host organism. After overnight incubation, the culture was centrifuged to clarity and the supernatant titrated by the agar layer method[3] using 1 per cent tomato dextrose agar for the top layer. Repeated single-plaque isolations ensured the purity of the phage suspensions.

Lysates are identified by a number corresponding to that of the *Lactobacillus* host. Phages 300 and 316

* Figures in brackets indicate number of strains tested.
Upper figure, number of strains with phage efficiency of plating equal to host strain.
Lower figure, number of strains on which only a lytic drop area was demonstrated.

are active on corresponding *L. casei* hosts; phage 356 is active on a strain of *L. casei* var. *rhamnosus*, and the remaining 11 phages were isolated on different *L. fermenti* strains.

Strains of *Lactobacilli* used were type specimens kindly supplied by Dr. M. E. Sharpe, of the National Institute for Research in Dairying, Reading, England, as well as strains isolated here from human saliva and identified by the methods of Rogosa *et al.*[5].

The host-range of the phages was determined by: (*a*) titration of 0·1 ml. of undiluted, and 10^{-2} and 10^{-4} dilutions of lysates (10^{8} plaque forming particles/ml.) by the agar layer method[3]; (*b*) spotting a large drop of the corresponding dilution in the middle of the plate once the top-layer agar had set. Results are presented in Table 1. Discrepancies are observed in the host-range of phages as determined by the two methods. In many instances an area of lysis is present where the undiluted drop of lysate was placed, but the plaque-forming titre of the phage on the particular organism is zero. This effect, which is specific and reproducible, always extends the intra-species and often the inter-species host-range. Dilution of the lysate before application of the drop in these cases never results in the area of the drop containing individual plaques but simply in the disappearance of the entire lytic area. This phenomenon was investigated by mixing the phage and the organism at 37° C. After a period of 20 min. for adsorption, an aliquot was quickly centrifuged to clarity and the supernatant titrated on the host strain for unadsorbed phage. Simultaneously, another aliquot was titrated for viable bacteria and unadsorbed phage plus infective centres on both the organism under investigation and the host strain. All titrations were completed within 30 min. after mixing. Results of a typical experiment are presented in Table 2. Abortive infection with killing of the organism provides an adequate explanation for the phenomenon. A similar phenomenon has been encountered with *Salmonella* and *Staphylococcus* phages[6], and in this laboratory with *Proteus* phages.

Table 2. INVESTIGATION OF PHAGE 222 WHICH PRODUCES A DROP AREA OF LYSIS ON *L. casei* 316 WITHOUT INDIVIDUAL PLAQUE FORMATION. ADSORPTION 20 MIN. AT 37° C.

Initial concentration *L. casei* 316	$7·0 \times 10^{8}$/ml.
Initial concentration of phage 222	$4·5 \times 10^{8}$/ml.
Multiplicity of infection	0·64
Free phage after adsorption	$5·8 \times 10^{6}$/ml.
Phage adsorbed (per cent)	98·7
Surviving bacteria	$3·6 \times 10^{8}$/ml.
Bacteria killed by phage infection (per cent)	48·6
Unadsorbed phage + infective centres on *L. casei* 316	0
Unadsorbed phage + infective centres on host *L. fermenti* 222	$1·0 \times 10^{7}$/ml.
Infective centres on *L. fermenti* 222	$4·2 \times 10^{6}$/ml.
Killed *L. casei* 316 not yielding progeny phage (per cent)	98·8

Results obtained by both methods of phage-typing serve to confirm some of the serological relationships encountered by Sharpe[7] and Sharpe and Wheater[8]. Thus *L. casei* phages 300 and 316 and *L. casei* var. *rhamnosus* phage 356 all act on different strains of *L. casei*, *L. casei* var. *rhamnosus* and *L. plantarum*. The former two phages also act on various *L. fermenti* strains. The serological relationship which was detected between *L. fermenti*, *L. casei* and *L. casei* var. *rhamnosus* strains may be mirrored in the fact that many of the *L. fermenti* phages also act on *L. casei* strains. Davis[9] includes *L. lactis* in his *L. acidophilus* group and Sharpe[7] found *L. brevis* and *L. lactis* to share a major antigenic component. It is thus of some interest to note that three *L. fermenti* phages acting on *L. brevis* strains also produce abortive infections in four homofermentative *L. acidophilus* strains. While Sharpe[7] has not indicated any serological relationship between the heterofermentative species *L. fermenti* and *L. brevis*, many phages isolated on the former lyse cultures of the latter.

It is too early to decide whether the extended host-range obtained for many phages by employing abortive infection will be desirable when a complete phage-typing scheme, comparable both in elegance and utility to those in use for *Salmonellas* and *Staphylococci*, is evolved for *Lactobacilli*.

This work is submitted with the permission of Prof. C. L. de Jager, honorary director of the Nutrition and Dental Health Research Group of the South African Council for Scientific and Industrial Research.

Association of Pigment with the Cell Envelope of *Serratia marcescens* (*Chromobacterium prodigiosum*)

THE characteristic red pigment of the bacterium, *Serratia marcescens*, is located within the cell. Recently[1] evidence has been presented demonstrating that disruption of the bacterial cell releases pigment that is bound to particles. However, the origin and location within the cell of the particles and associated pigment were not established. The present communication presents evidence that the particulate, pigmented material is associated with the cell envelope of the micro-organism.

The 'Nima' strain of *S. marcescens* was grown at 27° C. for 18 hr. on casein hydrolysate–yeast extract–agar medium[2]. The pigmented organisms were harvested, washed several times in distilled water, and then treated for 20 min. in a Raytheon model *DF* 101 sonic oscillator. Whole cells and large particles were removed from the treated material by centrifugation at 4,000 r.p.m. for 10 min. The supernate was centrifuged at 10,000 r.p.m. for 20 min. to collect cell envelope material. After this treatment both the sediment and supernate remained pigmented. An attempt was made to clarify the supernatant material by centrifugation at 40,000 r.p.m. for 2 hr. The slight amount of pigment remaining in the supernate following this procedure was precipitated by acidifying the fraction to pH 5·0 with 1 *N* hydrochloric acid. This treatment produced a flocculent, light red precipitate and a colourless supernate.

To study the possible association of pigment with cell envelope material, the acetylhexosamine and pigment content of the various sediments and the acid precipitate was measured. The preparations were lyophilized and 25-mgm. of the dried material utilized for the analyses. For hexosamine determinations, the precipitates were treated with lysozyme (400 μgm./mgm. dry material) at 37° C. for 30 min. Acetylhexosamine then was estimated by the Elson and Morgan procedure[3]. Pigment was extracted from the dried preparations by a modification of the alkaline method of Hubbard and Rimington[4], and the pigment concentration of the extract measured in a Klett–Sumerson colorimeter employing the number 42 filter. The same treatments also were applied to dried, whole-cell preparations.

Table 1 presents the results of these experiments. It is readily seen that the hexosamine and pigment values parallel each other. When the hexosamine content is low, so is the amount of pigment, and vice versa. The greatest values are obtained in the 10,000 r.p.m. sediment. Lysozyme treatment of whole cells released some hexosamine, but the amount was almost doubled in the 10,000 r.p.m. material. Similar experiments carried out with colourless cells grown at 38° C. also demonstrated that the greatest concentration of hexosamine was present in the 10,000 r.p.m. sediment. Electron microscopy of the 10,000 r.p.m. fraction showed that the material consisted of many cell envelopes and unidentifiable cell debris with only a very occasional whole cell.

Table 1

Preparation	Pigment	Acetylhexosamine
Whole cells	35	5·11
4,000 r.p.m. sediment	73	6·79
10,000 r.p.m. sediment	151	9·04
40,000 r.p.m. sediment	58	5·71
Acid precipitate	20	0·56

Pigment concentration is expressed as Klett units; hexosamine, as μgm./mgm. dry material.

The results suggest that hexosamine and pigment are present in the same cellular structure. This structure is released by rupture of the cell, and can be collected in greatest quantity in the 10,000 r.p.m. sediment. The cell envelope is such a structure. It has been repeatedly established that the cell envelope contains acetylhexosamine, which can be released by lysozyme treatment[5,6]. The fact that the cell fraction containing the greatest concentration of acetylhexosamine also contains the most pigment suggests strongly the association of the two substances with the cell envelope. The electron microscopic pictures support this conclusion. Additional experiments in which cell envelopes were prepared by the procedures of Salton and Horne[7] and Kandler *et al.*[8] have confirmed that the pigment is associated with cell envelope material. Spectroscopic examination of the 10,000 r.p.m. sediment and cell envelope preparations demonstrated the absence of nucleic acid or other material absorbing at 260 mμ. As pointed out by Work[9], lack of these substances is characteristic of purified cell envelopes.

Few investigations have been carried out to determine the intracellular location of bacterial pigments. Salton[10] has described the pigment of *Rhodospirillum rubrum* as being in the cell wall; but Hickman and Frenkel[11] doubt this observation. The latter investigators suggest that the observation was based upon an incomplete removal of protoplasmic constituents from cell wall fragments. Recently, Mathews and Sistrom[12] have localized the carotenoid pigment of *Sarcina lutea* in the cell or plasma membrane which, together with the cell wall, forms the cell envelope. Their evidence was based on visual and spectrophotometric examination of purified cell-wall material, upon lysozyme preparations of whole cells, and on the enzyme content of disrupted cell fractions. From the results we have presented, we cannot determine whether the pigment is located in the plasma membrane or wall portion of the cell envelope. However, the fact that lysozyme treatment of whole cells results in the release of a clear supernate containing hexosamine suggests that the pigment might be located in the cell or plasma membrane.

This investigation was supported by research grant E-670 from the National Institutes of Health, U.S. Public Health Service, and a post-doctorate fellowship in the Department of Microbiology (M. P.). We wish to thank Dr. J. C. Hampton of the Department of Anatomy for assistance in the electron microscopy.

MISCELLANY

Expression of Concentrations of Solutions

It is becoming customary, in the descriptions of histochemical methods, to express the concentration of solutions in terms not of percentage but of molarity. Thus, in one method, it is stated that a 0·004-*M* solution of lead nitrate should be used. Having eventually found a list of atomic weights and the formula of lead nitrate (it has, according to two textbooks, no water of crystallization) and then double-checked my addition, I discovered that in 100 ml. of distilled water I should dissolve 107·7 mgm. of lead nitrate.

But did the author use, as I obviously now do, a 0·1 per cent (0·003723 *M*) solution? If so, the term 0·004 *M* is inaccurate, time wasting and an example of scientific snobbery.

Surely it would prevent wasted effort and occasional inaccuracies if concentrations of solutions were expressed in terms not merely of molarity but also of percentage, particularly where the calculation of the percentage may prove troublesome.

FORTHCOMING EVENTS

Monday, July 25

Royal Society (at the Royal Institution, 21 Albemarle Street, London, W.1), at 10.15 a.m.—Sir Arnold Hall, F.R.S.: "Trends in Aeronautical Science and Engineering" (Tercentenary Lecture).

Institute of Metals (at the Royal Institution, Albemarle Street, London, W.1), at 6.30 p.m.—Prof. Linus Pauling (California Institute of Technology): "The Structure of Metals and Intermetallic Compounds".

Wednesday, July 27

Society for Endocrinology (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 5.15 p.m.—Prof. Bernardo A. Houssay (Buenos Aires): "An Argentine Trail in Hypophyseal Research" (Annual Lecture).

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer, Grade B, to teach either Mathematics or Physics to G.C.E. Advanced Level Standard—The Principal, Peel Park Technical College, Salford 5 (July 27).

Senior Technologist or Technologist (with H.N.C. or O.N.C. or appropriate City and Guilds qualification in telecommunications, and good experience on the maintenance and construction of electronic equipment and instrument maintenance) at the Nigerian College of Arts, Science and Technology—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (July 29).

Assistant, Grade "B" (preferably with teaching and/or industrial experience) in the Chemistry Department—The Principal, Wigan and District Mining and Technical College, Wigan (July 30).

Assistant Lecturer (with a degree in chemistry, biochemistry or agricultural chemistry, preferably with honours) in the Agricultural Chemistry Department—The Secretary, North of Scotland College of Agriculture, 41½ Union Street, Aberdeen (July 30).

Lecturer (graduate in science, preferably in physics, with suitable teaching experience) in Education—The Registrar, King's College (University of Durham), Newcastle upon Tyne 1 (July 30).

Lecturer (preferably with an interest in, and practical experience of, hydraulics or soil mechanics) in Civil Engineering—The Registrar, The Manchester College of Science and Technology, Manchester 1 (July 30).

Lecturer (veterinary surgeon) in the Department of Veterinary Pathology, Royal (Dick) School of Veterinary Studies—The Secretary, The University, Edinburgh (July 30).

Research Assistant (with a first- or upper second-class honours degree) in the Department of Agriculture (Crop Husbandry), to carry out sod-seeding experiments—The Registrar, University College of Wales, Aberystwyth (July 31).

Scientific Officer (with at least a good honours degree in geography with subsidiary zoology and/or botany, or in zoology with subsidiary geography) in the Geographical Section, for research in the biogeography of economically important locusts and grasshoppers—The Director, Anti-Locust Research Centre, 1 Princes Gate, Kensington, London, S.W.7 (July 31).

Assistant Lecturer or Lecturer (with qualifications in mining geology or mineralogy) in the Department of Geology—The Registrar, The University, Liverpool (July 31).

Assistant Lecturer, Grade B, in Biology or Chemistry—The Principal, Peel Park Technical College, Salford 5 (August 2).

Assistant Lecturer or Lecturer in Applied Mathematics—The Registrar, The University, Sheffield (August 3).

Assistant Biochemist (with a degree or equivalent qualification in chemistry, experience in, or wishing to take up, clinical biochemistry)—The Secretary, Welsh National School of Medicine (University of Wales), 34 Newport Road, Cardiff (August 6).

Lecturer in Mechanical Engineering—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (August 8).

Senior Lecturer in the Department of Studies in Psychological Medicine—The Registrar, The University, Liverpool (August 13).

Lecturer in Experimental Pharmacology—The Secretary of University Court, The University, Glasgow (August 15).

Lecturers in Botany, Chemistry, Education, Geology, Mathematics, Physics and Zoology at the University College of Townsville, University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, August 15).

Research Fellow (with at least a good honours degree, and preferably qualifications in both physics and geology) at the University College of Rhodesia and Nyasaland, for a research project in paleomagnetism—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 16).

Senior Lecturer or Lecturer in Mathematics, and a Senior Lecturer or Lecturer in Philosophy at Canberra University College, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, August 20).

Assistant Lecturer or Lecturer (with special qualifications in either pure mathematics or applied mathematics) in Mathematics—The Registrar (Room 22, O.R.B.), The University, Reading (August 22).

Lecturer or Assistant Lecturer (medically qualified or otherwise) in the Department of Physiology—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (August 22).

Lecturer in Chemistry at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, August 26).

Senior Lecturer in Biochemistry at the University College of the West Indies—The Secretary, Senate Committee on Colleges Overseas in Special Relation, University of London, Senate House, London, W.C.1 (August 29).

Chair of Education—The Registrar, University College of Wales, Aberystwyth (August 31).

Chair of Philosophy in the University of the Witwatersrand, Johannesburg, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, August 31).

Lecturer (interested in morphology and systematic botany) in Botany—The Registrar, The University, Hull (August 31).

Senior Lecturer in the Department of Mathematics, University of the Witwatersrand, Johannesburg, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, August 31).

Senior Library Assistant (graduate with library experience) in charge of the Current Periodical Room of the University Library—The Librarian, The Main Library, The University, Birmingham 15 (August 31).

Lecturer (preferably candidate who is a general botanist with research experience in more than one branch of botany) in Botany at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 2).

Reader in Chemical Crystallography at Imperial College—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 14).

Chair of Medicine at Makerere College, The University College of East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (September 15).

Chair of Psychology at Birkbeck College—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 16).

Administrative Assistant (with a language qualification) in the Section of International Relations, principally for information bureau duties—The Assistant Secretary, The Royal Society, Burlington House, Piccadilly, London, W.1.

Assistant Lecturer or Lecturer (preferably with an interest in climatology) in Geography at the University College of Ghana—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1.

Biochemist, for an interesting research project—The Group Secretary, Rochdale and District Hospital Management Committee, Birch Hill Hospital, Rochdale, Lancs.

Biochemist (preferably with some experience of techniques applicable to muscle or nucleic acids), to assist in a study of the location of ribonucleic acid in muscle by autoradiography—Mr. D. K. Hill, Postgraduate Medical School of London, Ducane Road, London, W.12.

Biologist (preferably 25–35, with experience and interest in lower organisms, particularly protozoa) for collaboration in a programme of research on fine structure, function and morphogenesis—The Director, Medical Research Council Biophysics Research Unit, King's College, Strand, London, W.C.2.

Computer, to work in a small team concerned with interesting research on thermonuclear processes—Prof. D. Gabor, F.R.S., Electrical Engineering Department, Imperial College of Science and Technology, London, S.W.7.

D.S.I.R. Research Student (honours graduate in physics or electrical engineering) in the Department of Electronics, for research into problems associated with microwave generation, electrical noise, electron spin resonance and nuclear magnetic resonance—The Professor of Electronics, The University, Southampton.

Lecturer or Assistant Lecturer in Chemistry—The Registrar, Massey Agricultural College (University of New Zealand), Palmerston North, New Zealand.

Lecturer or Senior Lecturer (with a university degree in medicine, and preferably with an interest in applied pharmacology and therapeutics) in Pharmacology—The Secretary, Charing Cross Hospital Medical School, 62–65 Chandos Place, London, W.C.2.

Lecturer (registered medical practitioner, with some experience of general pathology) in the Department of Neuropathology—Prof. W. Blackwood, Institute of Neurology, The National Hospital, Queen Square, London, W.C.1.

Research Assistant (with a first degree of the University of London and an interest in ultrasonics and electronics) in Ultrasonic Physics—The Principal, Kingston Technical College, Fassett Road, Kingston-upon-Thames, Surrey.

Research Biochemist (with good training in physical chemistry and preferably a knowledge of food technology of fruits and vegetables)—Dept. 4240, National Employment Service of Canada, 61 Green Street, London, W.1.

Research Fellow (preferably with experience in crystal or solid-state physics or in the physics of aerosols) in Experimental Physics, to work in a group investigating the basic physics of cloud and rain-forming processes—Dr. B. J. Mason, Huxley Building, Imperial College of Science and Technology, Exhibition Road, London, S.W.7.

Scientific Director (with three years post-doctoral research experience in nuclear reactions) of the Nuclear Physics Laboratory of the Institute of Physics and Mathematics, to lead research around an operating 800-kV. Cockcroft–Walton accelerator and to lecture on experimental and theoretical nuclear physics at the School of Physics at the University of Chile—Director, Instituto de Física y Matemáticas, Universidad de Chile, Casilla 2777, Santiago, Chile.

Tutorial Assistant (man or woman graduate) in Mathematics—The Registrar, The University, Leicester.

SCIENTIST AND TECHNOLOGIST IN ADMINISTRATION

A DEPARTMENT of Science and Technology in the Federal Government of the United States, headed by a cabinet secretary and responsible for a considerable range of scientific and technological activities, has been proposed in several recent Senate bills and recommended in varying forms by administrators of such scientific standing as Dr. L. V. Berkner and Dr. W. R. Brode. Early in January 1960, these proposals were discussed by a group which included Dr. Berkner, Prof. A. H. Dupre, Mr. D. K. Price, Mr. Dael Wolfle and three others. The group agreed in advance to concentrate on the reasons for considering such a department, the alternative forms it might take, and their probable consequences for science and engineering, and for the ability of the Federal Government to carry out its responsibilities in these fields.

The report based on these discussions which Mr. Wolfle was asked to prepare and which has been published in *Science* of May 13 (131, 1407; 1960) has thus an interest for scientists and technologists generally and not simply for those concerned with the relations between government and science in the United States. It makes a genuine attempt to arrive at first principles, and the Group's findings and comments have considerable relevance to the functions of the Minister for Science in Britain and the organization for which he is responsible. The arguments in favour of a Department of Science and Technology are carefully examined, the implications are indicated, and sound criteria are defined which can be applied to any changes in the structure by which scientific advice is brought to bear on problems of government, no less in Great Britain than in the United States.

The first major criterion for judging an organization is its ability to get the assigned jobs done as well as possible, and here the American Group clearly has grave reservations as to how far the proposed Department would offer advantages over the existing arrangements. It does not accept the view that complete elimination of duplication is a valid objective, nor does it consider that co-ordination is necessarily more effective through a single department, as against proper communication between a number of independent departments. Efficient organization is essential, and this applies to any such new department and to existing departments or agencies the activities of which require co-ordination. Both principles are to be kept clearly in mind in considering the activities and interrelations for which the Minister for Science is responsible and also for some, like those in the fields of defence and of education, for which direct responsibility lies elsewhere. It is, in fact, precisely because some recent developments have raised doubts as to the operational effectiveness of the Defence Research Policy Committee and the efficiency of the organization of higher technological education under the control of the Minister of Education and the local authorities, that changes have been suggested for Britain.

Again, the Group rejects the argument that establishment of a Department of Science and Technology would increase financial support for such activities. Such support from public funds, it is rightly pointed out, must come from an increase in public understanding, though the Group accepts as probably sound, though not compelling, the argument that establishment of such a Department would enhance the status of science and technology as a government activity. Here again much depends on effective public relations, and it seems probable that if the existing official research councils in Britain are adequately financed and their activities effectively interpreted to the general public, the Minister for Science should be able to command sufficient public attention and prestige for the activities for which he is responsible. That undoubtedly comes first, for immediately science begins to affect policy, public understanding is imperative.

This appears clearly enough from the fourth criteria which the Group applies to the organization of scientific and technological activity—a capacity to promote the development of sound policy. Scientific and technical activities constitute one of the elements that must be considered in many aspects of broad national policy. At some point in the structure of government there must be means for bringing all the scientific and technological threads together, both from the point of view of establishing policy for research and development agencies and from that of the contributions these agencies make to national policy.

The Group is emphatic that guidance of policy should not mean centralized direction of the work of individual scientists, though it points out that research is not wholly a matter of individual decisions. With the increasing cost of equipment and facilities, it becomes a matter of general policy to decide what new facilities can be afforded, which are likely to make the greatest contributions to science, and which to the attainment of other national objectives. From this aspect of policy-making—the provision broadly for the advancement of science and its practical applications—arises the debate as to how far Britain should engage in space research or nuclear physics research, and the scale of any such effort relative to that, for example, in biochemistry or medical research.

This is the first class of policy problems which the Group distinguishes. The next comprises the contributions that scientific and technical knowledge can make to the solution of other national problems. In illustration the report quotes the ability to detect nuclear explosions, and the bearing of this ability on decisions concerning disarmament and inspection. A third class includes the influence of national needs on science and technology. Political, military and economic needs all help to determine the emphasis given to different technological areas and even to different fields of research.

The report argues that whoever has responsibility for making decisions on these inter-related issues must have opportunity and authority to review the entire research and development effort of the nation, and to give due consideration to other issues of policy; the fundamental question before the Group was whether the proposed Department would provide the means for this, and even ensure a drastic improvement in the capacity of the Federal Government to cope with scientific and technical problems. With this in mind, the reports sets forth the alternative possibilities. It rejects as unworthy of serious consideration any proposal that all the research and development activities of the U.S. Government shall be brought together in one Department. Scientific and engineering activities that are intimately related to the operating responsibilities of an agency belong to that agency: research on military problems, for example, cannot wisely be divorced from the Department of Defence. Again, science and technological development have so much in common and benefit so much from each other, in any particular area, such as nuclear energy, that the two should remain under the same administrative direction.

These two principles appear to have been recognized in at least some of the proposals advanced in the United States. Dr. Berkner, for example, excluded research and development activities which are an integral part of the agencies in which they are at present located—for example, the Departments of Agriculture and Defence—as well as agencies which are primarily responsible by supporting research carried out by others. He would also exclude independent agencies that are already strong and command firm support, such as the Atomic Energy Commission and the National Aeronautics and Space Administration. In the United States this would leave a group of scientific and technical bureaux which Dr. Berkner believes could be moved without detriment to the departments in which they are already located, though there is no obvious title for the new single Department. The main advantage would be that, through the closer contact thus established, the scientific and research activities would be stimulated and the new Department could be given responsibility for the development of new scientific activities. A Department devoted wholly to scientific and technical activities would, he suggests, be more likely to be on the alert to identify areas that need special emphasis, and more eager to secure the facilities that are required.

The proposal was not accepted without modification by the Group. The report that Mr. D. Wolfle has compiled, while agreeing about certain exclusions, suggests that the National Aeronautics and Space Administration should be included, and possibly also the National Science Foundation. None of the proposals for a Department of Science and Technology was regarded as entirely satisfactory, though each helps to reveal deficiencies in the present administrative structure. Dr. W. R. Brode's proposal for a Department of Science, for example, while accepting the general principle that scientific activities essential to the work of an operating agency should be left in that agency, is designed to correct the tendency for authority to engage in basic research in fields that underlie an agency's operating responsibilities, thus supporting an unnecessarily wide range of scientific activities. This was the substance of some serious criticism in Britain of Admiralty research advanced in reports from the Select Committee on Estimates. Dr. Brode's Department of Science, while not removing from agencies such as Defence and Agriculture the research programmes specific to their missions, would include all major segments of science not specifically pertinent to those missions.

Even with the sound principles endorsed by this report, the real difficulties lie in deciding where to draw the line, and in finding the balance of advantages and disadvantages in any change of organization. The Group recognizes very clearly, for example, the value of having alternative means of allocating funds, particularly in fundamental research, as well as the difficult decisions which have to be taken about entering new fields. Here, however, its major emphasis is on the need to watch for new developments, and, whether or not a Department of Science and Technology is established, the report stresses the urgency of achieving greater competency for looking ahead to identify and develop those areas of research that are not yet the responsibility of one of the applied science agencies but that appear likely to produce major advances and applications in return for special support. It might well have been added that closely allied is the no less difficult problem of deciding when to discontinue such support and where the responsibility for continuance or discontinuance should lie.

There is little in all this to point to any need for basic changes in the present structure of Britain's organization for securing that due account is taken both of scientific and technical factors in the making of policy and for securing effective co-ordination of such activities and reasonable allocation of resources for such purposes. Broadly speaking, that is the purpose of the creation of a Ministry for Science, and the report provides substantial reasons for doubting whether that purpose will be better achieved by giving the Minister more executive responsibilities in fields which lie outside his present responsibilities, but not his interest, as in defence research. More is likely to be achieved by strengthening the informal links which at present exist, as between the Advisory Council for Scientific Policy and the Defence Research Advisory Committee, for example, between the several research councils themselves and between them and the universities and industry, and also by positive measures, through the Parliamentary and Scientific Committee and in other ways. In this way it may be possible to create an informed public opinion prepared to provide and maintain the necessary support, competent at least within certain sections to criticize soundly, and one which also sufficiently recognizes the value and significance of science in Government to ensure that the question of status no longer arises.

There are, however, major considerations in this matter of determining overall scientific policy to which the American report directs attention. The limits within which existing or new means of presenting scientific or technological advice can function must also be recognized. Scientific and technological factors are only one element, even if an important one and on occasion the deciding factor in determining national policy. There are financial, economic, social and other factors to be considered, and in this the political element—and frequently the party political element—enters and cannot be excluded. For this reason, as the report points out, in the United States the centre of responsibility for policy must be close to the President, and this would be unaffected by the creation of any new Department of Science and Technology.

What matters is that for the Office of the President to possess the competence to exercise that role wisely, its staff must include men who are highly skilled in the management of scientific affairs, and who can relate scientific matters to all the other considerations that are involved in major decisions on policy. In this connexion it should be noted that the Group stresses the distinction between the position of Special Assistant to the President for Science and Technology and that of the Chairman of the Science Advisory Committee. Even though the two positions may be held by the same man, they are quite distinct. The Committee and its chairman should very properly place first emphasis in their thinking on the scientific and technological needs of the nation and the national implications of scientific and technological developments, and should be free to criticize established or proposed policy if damage to the nation's research and development programme is foreseen. In contrast, the Special Assistant is part of the Presidency, and must always subjugate specifically scientific or technological factors to the total of those involved in making a political decision—that is, a decision on policy. "Whether the chairman and the Special Assistant are the same man or different men, the President needs the best scientific and engineering advice available, and thus needs an Assistant for Science and Technology who can help him to weigh, judge, incorporate, and perhaps override that advice in establishing national policy."

The significance of this observation is obvious. In Britain, the Minister for Science provides the appropriate means for performing for the Prime Minister and in the Cabinet this latter function of the President's Special Assistant for Science and Technology, and it appears to rest with him also to see that through the Advisory Council for Scientific Policy and in other ways he is provided with the advice he needs for doing so. There appears to be no reason to doubt the adequacy of existing arrangements in Britain; but in the United States there seems to be room for improvement in the Federal Council for Science and Technology, and the Group appears to have had the personal factor more particularly in mind. So far as Britain is concerned, it would be difficult to suggest anyone better qualified than the present Minister for Science for presenting scientific and technological factors at ministerial level. Far more important at this level than scientific training is the ability to appreciate a situation as a whole, to work effectively with others and to present the scientific and technical issues clearly and relevantly. It is rather at the level of the advisory committees and councils and at the administrative level in the departments that the question of scientific training and administrative ability arises.

The American report commends for consideration the idea of having within each department an assistant secretary, or officer of similar senior rank, responsible for all research and development activities, and of using these officers as a strong co-ordinating council. Whether such a step would offer any advantage in Britain may be questioned. It would obviously tend to overlap the work of some of the existing advisory committees and councils and possibly to blur responsibilities and functions. Much more important seem to be the quality and the training of administrators in such posts, and the quality of the membership of the advisory councils and committees. This last in turn is linked to the question of status. Men of outstanding ability and experience and judgment will not be found to serve upon them unless the work is seen to be effective and their representations are treated with respect, even when in particular situations other factors may lead to their advice being over-ridden.

On the first problem, however, the question whether scientists rather than administrators as such should occupy more of the key posts in departments concerned with research and development merits more examination than the Government has been disposed to give it. Whether or not such an administrator is primarily a scientist, it is undeniable that it is increasingly impossible for him to be effective unless he has received sufficient scientific training and acquired sufficient scientific knowledge to appreciate the relevance and significance of the scientific or technical advice presented to him. Administrative ability is the primary criteria, but much more could well be done in the Civil Service to ensure that for scientists and technologists with the essential administrative flair there is full opportunity to rise to the highest posts. It does not speak well for the Government's handling of present conditions that there should be signs of such obvious discontent as the simultaneous day's leave taken by eight hundred of the scientific staff at Harwell last March, or the protests voiced at the recent annual conference of the Institution of Civil Servants.

It is true that, as a long article, "Scientists versus Administrators: an Approach towards Achieving Great Understanding", by Mr. Z. M. T. Tarkowski and Miss A. V. Turnbull in *Public Administration* last autumn shows, the Treasury is now giving some attention to this question, and residential conferences for senior scientists and administrators on organization and management have been arranged in the Civil Service for some years in which administrators, scientists and professional staff have been mixed in about equal proportion. The promotion of such understanding, like the promotion of effective co-operation and co-ordination, is, however, largely a matter of providing appropriate conditions, and it might well be worth while for Lord Hailsham to give some attention to this aspect and to the removal of the obstacles to which attention is directed in this article, particularly perhaps to the provision of facilities for scientists to obtain administrative training and experience.

The Beginning of the Royal Society

By Margery Purver and Dr. E. J. Bowen. Pp. 16+2 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1960.) 2*s*. net.

The Royal Society

Its Origins and Founders. Edited by Sir Harold Hartley. Pp. ix+275+29 plates. (London: The Royal Society, 1960.) 35*s*.; 6 dollars.

A Brief History of the Royal Society

By Prof. E. N. da C. Andrade. Pp. iii+28+14 plates. (London: The Royal Society, 1960.) 10*s*. 6*d*.; 2 dollars.

ONE of the most striking features of the preparations for celebrating the tercentenary of the foundation of "a Colledge for the promoting of physico-mathematicall-experimentall learning" which in 1662 became the Royal Society has been the flood of articles on the history of almost every aspect of this great enterprise and of those activities which were afterwards associated with it. To the three works published during the tercentenary celebrations there will rightly be attached a special importance. To "The Beginning of the Royal Society", which alone of the three does not carry the Society's imprint, there may also be attached a certain notoriety since it unambiguously asserts what "Origins and Founders" implicitly denies, namely, that the Royal Society 'began' in Oxford. Though the adoption of an 'official' version would be wholly at variance with the spirit of the Royal Society, it is the case that three of the four histories of the Society written by its officers—Birch, Weld, and Lyons—all adopted the statement of Wallis against Spratt (the fourth) that the Society's "first ground and foundation" was in London. The authors of this "agonizing reappraisal", in claiming that Sprat "speaks with the voice of the contemporary [1665] Royal Society", do not add that Sprat himself freely admitted that the "objections and cavils" against the Society had compelled him to write of it "not altogether in the way of a plain history but sometimes of apology". The "voice" of the propagandist—whether individual or corporation at a critical moment of its existence—is scarcely likely to be an infallible guide in the establishment of historical truth. In support of their thesis the authors have assembled a great deal of evidence relating to the activities of the 'philosophers' at Oxford before 1660. To me it seems regrettable that this impressive picture of the high significance of Oxford in the growth of the idea which finally took shape in the Royal Society was coupled with the dogmatically presented claim that the Society 'began' there.

"Thoughts," wrote A. N. Whitehead, "lie dormant for ages, and then almost suddenly, as it were, mankind finds that they have embodied themselves in institutions." To me it is the great strength of Prof. D. McKie's long 'leading' article on "Origins and Foundation" that it reveals the Royal Society as the embodiment of a thought which had no beginning, but whose emergence in seventeenth-century England was the final act of a process discernible under various forms in the previous two centuries. The almost "sudden embodiment" was due to a combination of the genius and devotion of a few individuals and a particular historical situation. The latter, in Prof. McKie's judgment, was the influx into London of several influential Royalists (such as Viscount Brouncker and Sir Robert Moray) with a taste and aptitude for "natural philosophy"; the deployment of the former is the concern of the rest of this admirable volume. Of the twenty-one biographies included twelve are those of the men whose recorded decision is the only indisputable 'beginning' of the Royal Society (John Wilkins, Jonathan Goddard, William Petty, Christopher Wren, Laurence Rooke, Robert Boyle, Viscount Brouncker, Paul Neile, William Ball, Abraham Hill, Robert Moray, and Alexander Bruce). The remainder are of men who, though absent from that decisive meeting, were from a very early date associated in the most intimate manner with the Society's well-being: John Wallis, though an infrequent attender at meetings, of international renown and a scholar of the highest calibre and integrity; Thomas Willis and William Croone, pioneers of experimental medicine—the latter also being "named for Register"; Robert Hooke and Henry Oldenburg, without whose complementary talents and devotion the "first fine frenzy" might have evaporated; and John Evelyn, by whose suggestion the Society was granted its Royal title. The two remaining—Kenelm Digby and Elias Ashmole—were indeed less intimately associated with the Society, but their importance for the understanding of the climate of opinion of the times fully justifies their inclusion. There is no space even to name the authors of these biographies, let alone to touch on their several merits. For the sustained enthusiasm which must have been brought to the task—evidently far greater than usually falls to the editor of such a symposium—the Republic of Letters will owe a permanent debt to Sir Harold Hartley: it will be best discharged by following the advice of the printer of Copernicus—*eme, lege, fruere*.

Prof. Andrade's booklet falls into a somewhat different category. His aim is to present a portrait of the Royal Society as a living organism active in the advancement and dissemination of natural knowledge; independent of State control, but ready to enlist State aid for projects likely to promote those ends. Since the life of an organism is determined by its mode of growth, Prof. Andrade has drawn freely on his great knowledge of the commanding figures of the past; but since no chronological sequence is maintained the title might be thought somewhat misleading. This however is a small matter; if the aim is here correctly described, the achievement could scarcely have been bettered.

William P. D. Wightman

GENETICS FOR BEGINNERS

An Introduction to Genetics

By Dr. C. M. M. Begg. (Biological Science Texts.) Pp. xi+292. (London: The English Universities Press, Ltd., 1959.) 35*s*. net.

THIS is a valuable addition to introductory text-books on genetics, suitable for undergraduates and for the reader with some knowledge of biology. It covers a wide range, from formal genetics, population genetics and evolutionary theory to the biochemistry of gene action. It is attractively produced, easy to read and lavishly illustrated with large, clear diagrams which form an integral part of the text.

It is a measure of the rapidity of growth in genetics that the chemical structure of nucleic acids in the chromosomes can now be discussed in an elementary text-book of genetics, and Dr. Begg is to be congratulated on discussing this and other questions which are not yet fully understood, and making it clear to the reader why they are not understood. This is always exciting and provoking in an introductory book. It is therefore surprising that he should have avoided a fuller discussion of the structure of the genetic unit and the nature of mutation and left the reader high and dry over the interrelationship of deoxyribonucleic acid and ribonucleic acid. It is nowhere made clear that ribonucleic acid is found both in the nucleus and cytoplasm nor that proteins always occur with the deoxyribonucleic acid in the chromosomes. This makes it difficult for the reader to effect a synthesis between the first and last chapters.

There are several misprints which may well lead the beginner astray, for example an extra plus sign has appeared in Fig. 97, and it is to be hoped that the problems posed in the references in the last chapter are not an introduction to the stated problems, with solutions, which follow.

It is a pity that small points of editing should have been allowed to mar an otherwise useful book, a book in which a great deal of effort has been made to use genetic examples from man and to emphasize that genetics is of interest to us all.

WILMA GEORGE

IDENTIFICATION OF BLOOD-GROUP ANTIGENS

The Anti-Globulin (Coombs) Test in Laboratory Practice

By Dr. I. Dunsford and Jean Grant. Pp. xiii+120. (Edinburgh and London: Oliver and Boyd, Ltd., 1959.) 12*s*. 6*d*. net.

THE antiglobulin test of Coombs introduced in 1945 was, in fact, a rediscovery, for so long ago as 1908 its principles were worked out by C. Moreschi, an Italian. Dr. Coombs was unaware of this when he introduced his test, but later he duly acknowledged Moreschi's work. The test, as devised by Coombs, Mourant and Race in 1945, is now very extensively used both in routine investigations and in research work.

Many important and substantial advances in blood group serology, that is, the identification of blood-group antigens in the cells, and isoantibodies in the serum (or plasma), would not have been possible without the Coombs antiglobulin test. In selecting blood for transfusion the Coombs test is quite the most reliable compatibility test thus far devised. This test has also proved to be extremely useful as a research instrument and, in particular, has proved invaluable in affording us a better understanding of hæmolytic anæmias. This book, written by two experienced workers, reflects the experience generally not only of the Oxford and Sheffield regional transfusion laboratories but, also, that of other transfusion laboratories. It gives an informative account of the Coombs test, the preparation of antiglobulin sera, the applications of the test, and there is a comprehensive list of references for those who wish to read further on the subject. Certainly this book will be very useful to every pathologist and technician who operates a blood bank.

A suitable account of antigens and antibodies is given, their detection by the Coombs test, and the serological basis of this test. The production, processing, and standardization of anti-human-globulin sera, the behaviour of such sera in tests, the technique and applications of the Coombs test, and the various snags which may arise, are all competently dealt with. The authors point out that antiglobulin sera prepared by heating or by dilution may be adversely affected in that they may be suitable only for detection of γ-globulin coatings. The application of Coombs's test in fields other than blood-group serology, for example in bacteriology, forensic medicine, hæmolytic disease in animals, etc., are briefly but adequately dealt with. This is a useful little book, being compact and concise, and it is to be hoped it will be kept so in future editions which will surely be required.

R. DRUMMOND

EVOLUTION OF MODERN EDUCATION

Studies in the History of Education 1780–1870

By Brian Simon. Pp. 375+24 plates. (London: Lawrence and Wishart, 1960.) 37*s*. 6*d*. net.

THE history of education often lends itself well to a Marxist analysis, and in the case of Mr. Simon's book it has undoubtedly helped to throw fresh light on British social developments in the nineteenth century. What makes this approach exasperating as well as rewarding is its tendency to straight-jacket the material, thereby first illuminating it and then obscuring it—the former by catching it in a sharp focus, the latter by distorting it to fit into a partial pattern of vision.

During 1780–1870 there was indisputably a vast social change, in relationship to which educational principle and practice stood as both cause and effect. Political and economic power shifted from the land-owning aristocracy to the Whig magnates and then, in step with technological invention, to an increasingly prosperous middle-class. This was reflected first in the attack of the Philosophical Radicals on the former establishment in Church and State up to 1832, and secondly in the building up of social institutions in favour of the liberal interest after that date and against the extension of full human rights as yet to the rest of the populace. A trifle tedious in connexion with the first of these phenomena, Mr. Simon's writing seems to catch fire as in Chapters 4 and 5 he describes the response educationally of the still unemancipated section of the nation. Particularly good are his portrait of William Lovett as an educationist and his definition of the links between the educational and more broadly political aspirations of the Chartists.

The following passage on page 223 reveals both the strength and the weakness of the author's arguments: he quotes from the *Northern Star* (1848) a rebuke by the workers to those who in their eyes had betrayed them:

"In our day, the Educationists are still what they were in Cobbett's time—the pretended friends, but the real enemies of the people . . . Ah gentlemen, we see through your craft . . . You would educate us, not, as you sometimes pretend, to fit us for the exercise of political rights, but to make us indifferent to those rights. And you call yourselves 'Philosophical Radicals'."

"This uncompromising statement," comments Mr. Simon, "epitomises the reaction of the most advanced section of the working class to the educational tactics of the bourgeoisie." The author's strength lies in his belief in and capacity for using a partial point of view in order to invest a series of historical events with meaning: his weakness lies in a too doctrinaire use of the viewpoint. Such a phrase as 'the educational tactics of the bourgeoisie' implies the ascription of far too conscious and unitary motives to what was a non-homogeneous and changing stratum of society. It merely serves to conceal the more difficult truth that, as Homyakov expressed it, "Only that is conservative which moves forward, and only that is progressive which does not break with the past". Mr. Simon's carefully documented book with its telling illustrations should help perceptive students of English nineteenth-century educational history to assimilate that paradox. JAMES L. HENDERSON

NUCLEAR MAGNETIC RESONANCE

High-resolution Nuclear Magnetic Resonance

By J. A. Pople, W. G. Schneider and H. J. Bernstein. (McGraw-Hill Series in Advanced Chemistry.) Pp. xii+501. (London: McGraw-Hill Publishing Company, Ltd., 1959.) 104*s*. 6*d*.

AT some stage in the development of almost every specialized physical technique of chemistry there has appeared a text-book which has ultimately become recognized as a standard work on the subject. Such books play a very important part in the practice of chemistry because they invariably provide a convenient source from which the underlying principles of the subject to which they pertain can be mastered. It is therefore most fortunate that the technique of high-resolution nuclear magnetic resonance, which is so obviously destined to be of major importance in chemistry, has acquired a standard text so early in its history, for certainly "High-resolution Nuclear Magnetic Resonance" will admirably fill this role.

This book is the result of a fruitful collaboration of a theoretician and practical spectroscopists, and as such provides a well-balanced account of basic theory, experimental technique, and practical applications. The first part of the book, entitled "Principles", deals with theory and its relation to experiment, and includes brief, but sufficient, descriptions of actual spectrometers. An elementary knowledge of quantum mechanics is necessarily assumed and on this basis the principles of the subject are developed concisely and with considerable clarity. The only serious criticism of Part 1 concerns the generalization made in section 4–8 to the effect that the preferred method of standardizing spectra uses an external reference. Even in 1958 it was more or less recognized that suitable internal references offer considerable advantages.

Part 2 deals with the complete range of applications of high-resolution nuclear magnetic resonance to chemical problems. As the book contains comparatively few references after the first six months of 1958 the real power of proton spectroscopy is not fully indicated. Indeed, it might be argued that the two parts of the book should have been published as separate volumes on the grounds that the contents of Part 2 cannot possibly remain representative of the subject for more than one or two years, and that many private purchasers might have been glad of obtaining Part 1 at a reduced price. Nevertheless, the later chapters of the book contain much which will be of considerable interest and help to both the expert and uninitiated reader.

Such criticisms as have been made above are of minor significance compared with the stimulus which this book is already giving to a rapidly expanding subject. Certainly every worker in the field of nuclear magnetic resonance will need to know and use this book, and those in other disciplines will consult it on numerous occasions. Finally, the authors and publishers are to be congratulated on the uniformity and excellence of the presentation.

L. M. JACKMAN

PRINCIPLES AND PRACTICE OF TELEVISION ENGINEERING

Television Engineering

Principles and Practice. By S. W. Amos and D. C. Birkinshaw. (B.B.C. Engineering Training Manuals.) Vol. 1: Fundamentals, Camera Tubes, Television Optics, Electron Optics (written in collaboration with J. L. Bliss). Pp. 302 (1953). 30*s*. net. Vol. 2: Video-Frequency Amplification. Pp. 270 + 5 plates (1956). 35*s*. net. Vol. 3: Wave-form Generation. Pp. 226 (1957). 30*s*. net. Vol. 4: General Circuit Techniques. Pp. 268 (1958). 35*s*. net. (London: Iliffe and Sons, Ltd.; New York: Philosophical Library.)

THESE four volumes form a comprehensive guide to the principles and practice of television engineering produced by authors who have actively participated in the development of the B.B.C. television services for many years past. The series has been produced from text-books prepared primarily for instruction of the Corporation's own staff, and they are now made available for a wider technical public.

The first volume deals with the fundamental principles of converting a visual scene into electrical signals for transmission to a distant receiver. Considerable space is given to a description of the various types of television camera tubes, and a discussion of the principles of the transmission of light by lenses and mirrors, and of the analogous problems encountered in electron optics. Volume 2 is devoted to video-frequency amplification at both high and low frequencies, with some reference to the sources and nature of noise associated with camera-head amplifiers. In this case, the text is rather more mathematical than in the first volume; but a wide variety of circuits is described, including the use of feedback. Numerical examples are given to illustrate the application to practical equipment.

A somewhat similar presentation is adopted in the third volume, which covers the subject of wave-form generation for television transmission. Separate parts of this book are devoted to the production of waves of sine, rectangular, sawtooth and parabolic form, with details of the various types of valves and circuits suitable for these. The multi-vibrator, in one or other of its different forms, naturally plays a large part in this technique as applied to the reception and analysis of television signals.

The fourth and last volume of this comprehensive work deals with a wide range of circuit techniques, many of which are applicable to the general field of electronics as well as to television engineering. Among the techniques treated are counter circuits, frequency dividers, direct current clamping and restoration, and amplifiers, delay lines and equalizers. Some of these subjects require a mathematical treatment but, in order to facilitate the presentation of the text, many of the mathematical derivations are given in appendixes to the individual chapters.

Altogether these four volumes form a most valuable aid to those engaged in the science and application of the generation and use of television signals, and allied fields of electronics. The texts are very clear throughout and well illustrated by graphs and schematic circuit diagrams. The production of the volumes is of a high standard and is a credit to the publishers as well as to the technical staff of the British Broadcasting Corporation. The work can be confidently recommended as a guide to circuit designers, as a training manual to lecturers and as a general work of reference to the radio and electronics engineer.

R. L. Smith-Rose

UNIFICATION OF ANALYTICAL APPROACHES TO ENGINEERING PROBLEMS

Engineering Systems Analysis

By Prof. Robert L. Sutherland. (Addison-Wesley Series in Instrumentation and Control.) Pp. xii+223. (Reading, Mass.: Addison-Wesley Publishing Company, Inc.; London: Academic Books, Ltd., 1958.) 60s.

THE unification of the analytical approach to engineering problems is an ideal which is sometimes attempted in advanced texts on certain branches of engineering science. It is not, however, very commonly attempted in text-books for undergraduates. Clearly there is a major difficulty in limiting the scope of such a work and in selecting the material to be included. It is, therefore, particularly interesting to find an undergraduate text-book under the title "Engineering Systems Analysis".

The book opens with a study of basic electromechanical analogies and then proceeds to a consideration of mechanical vibrating systems. This is followed by a chapter on oscillations in electrical networks. A section dealing more generally with dynamical systems develops the method of treatment for mixed systems with electrical and mechanical components and explains the use of dimensionless ratios. Dimensional analysis is then treated in considerable detail and its application is illustrated by examples in the field of hydro-dynamics. Thereafter follows a section on the principles of feedback and control and the book concludes with a chapter on analogue and digital computing machines.

With such a wide coverage it might be thought that the treatment would be too superficial to be of real value. In fact the author has succeeded in dealing with a selection of fundamental topics in quite sufficient depth and at the same time in producing a coherent whole. This has in large measure been achieved by the judicious selection of his illustrations.

It would appear from the author's preface that this text-book will meet the needs of certain courses which are being developed in universities in the United States. It is a little difficult to see precisely where this book would fit into the structure of most British undergraduate courses in engineering. None the less, the unification of treatment which is achieved is something of intrinsic value which merits the attention of undergraduates, and the book can certainly be commended as basic reading for both mechanical and electrical engineers. The standard of mathematics involved should be well within the competence of the British undergraduate in his second year.

J. Greig

RUBBER TECHNOLOGY

Introduction to Rubber Technology

Edited by Maurice Morton. Pp. v+547. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1959.) 80s. net.

AN "Introduction to Rubber Technology", edited by Prof. M. Morton, of the Institute of Rubber Research of Akron University, Akron, has first to be compared with the standard work on "Synthetic Rubber" edited by Morton's predecessor, G. S. Whitby. "Synthetic Rubber" is primarily concerned with the preparation and uses of the general purpose styrene-butadiene rubber, with relatively brief mention of chloroprene, nitrile, and butyl rubbers. "Introduction to Rubber Technology" devotes the same fraction of its space to styrene-butadiene rubber as to each of the other rubbers considered. There is no case, therefore, to regard the new book as overlapping seriously the older.

After introductory chapters on the history of rubber technology and polymer chemistry, separate chapters deal with natural rubber, butadiene-styrene, nitrile and acrylate, butyl, polychloroprene, chlorosulphonated polyethylene, polysulphide and silicone rubbers. The various types of rubber additives—plasticizers, antioxidants, and anti-ozonants, accelerators, and fillers—are also treated in separate chapters. Articles on reclaimed rubber, latex and sponge rubber, physical testing, and processing equipment round off a broad survey of modern rubber technology. The only serious omission appears to be of the new polyurethane and polyether foams.

Morton has achieved a large measure of success in welding together the efforts of twenty contributors. The technical level of the articles is uniform and makes for a very readable book. The material is up to date, and presents for the first time in book form much information of value to rubber technologists in

Britain. The quality of printing and of the illustrations is first-class.

The question does arise as to whom this book is directed. It will probably be disappointing to specialists in other fields who seek from the title an introduction to rubber technology within the framework of chemistry and physics. The policy appears deliberate of keeping the scientific matter on a 'popular' level. For example, in the chapter on polymer chemistry, one jumps within a page from atoms and valency to monomers and polymers. Again, in the chapter on vulcanization, the concept of cross-linking is dismissed with reference to the analogy of a fish net of varying size of mesh, and no concept is given of the number of cross-links to monomer units or dependence of properties on the nature of the cross-links, to take only two relevant subjects which should surely be dealt with. The popular approach is also sometimes misleading, as in the equations put forward to describe rubber oxidation.

Rather than an 'Introduction', the various chapters of this book are really self-contained reviews. As such, they include much of interest to practising rubber technologists. The readers of this book will, in general, be already qualified and could with ease have swallowed stiffer doses of the science of their subject from the eminent contributors to this volume. A chemistry and physics of rubber technology still requires to be written. W. F. Watson

MARINE BIOLOGICAL REPORTS FROM DENMARK

Meddelelser frå Danmarks Fiskeri- og Havundersøgelser

Ny Serie, Bind 2, Nr. 23–26. Nr. 23: Investigations on the Quantitative and Qualitative Distribution of Zooplankton in the Southern Part of the Norwegian Sea. By V. K. Hansen. Nr. 24: A Quantitative Investigation of the Echinoderm Fauna of the Central North Sea. By Erik Ursin. Nr. 25: Conditioning *Ostrea edulis* L from the Limfjord for Reproduction out of Season. By I. A. Aboul-Ela. Nr. 26: The Oligochaete Fauna of Three Danish Brackish Water Areas. By I. Dahl. Pp. 292+5 plates. (København: C. A. Reitzels Forlag, 1960.) 47 Danske kr.

The final part of the second volume of the new series of biological reports published by the Danish Institute for Fisheries and Marine Research contains four interesting contributions which carry on the high standards established by the earlier series. The first paper, by V. K. Hansen, "Investigations on the quantitative and qualitative distribution of zooplankton in the southern part of the Norwegian Sea", describes the results of cruises made during several seasons in the area of the off-shore herring fisheries just north of the Iceland–Faeroes–Shetland ridge. Samples were taken with the vertical Hensen net, supplemented by horizontal hauls with small high-speed samplers of the Hardy Indicator type. The catches are described and discussed in relation to movements of Arctic and Atlantic water masses, but conclusions are apparently being kept until the remainder of the plankton community has been described.

Of two shorter papers, one by I. A. Aboul-Ela, on "Conditioning *Ostrea edulis* L., from the Limfjord for reproduction out of season", shows that successful spawning can be induced by higher temperatures. The other paper, by Mrs. Ingerlise Dahl, on "The Oligochaete fauna of three Danish brackish water areas", deals with the systematics and biology of these little-studied animals, which form a surprisingly important component of the bottom fauna in the Danish Fjords.

Most of the volume is taken up by Dr. E. Ursin's comprehensive study, "A quantitative investigation of the Echinoderm fauna of the central North Sea". The author has based his work on most of the Danish material collected since 1922, as well as on a large number of quantitative grab-samples taken from R.V. *Dana* during 1950–55. Full tables are given showing the occurrence of the commoner species at all stations since 1932, and the distribution of both common and rare forms is described in some detail. Reference is made to the accepted bottom fauna communities, but in the main the distributions are considered from the zoogeographical point of view in comparison with other localities, notably Iceland and the Adriatic. Apparently the echinoderms of the southern North Sea have decidedly southern affinities, and the total numbers per unit bottom area are considerably greater than in the northern part. However, the author regards the latter area as the rich area for echinoderms because a larger number of (rarer) species occur there. Many of the species found only in the northern (or north-western) part of the North Sea are distributed to the north of the area (for example, *Leptasterias mülleri*, *Strongylocentrotus droebachiensis*), and would thus be expected to be limited to the northern region because of the generally cooler conditions there during the summer months and the somewhat deeper water which allows the establishment of a thermocline. Other, much fewer, species of southern distribution outside the North Sea (for example, *Antedon bifida*, *Palmipes membranaceus*) are also limited to the same area as the cold-water forms, possibly, it would be expected, because they can better survive the colder months of the year there than farther to the south and east where there are greater extremes of climate. However, the author, after considering such hypotheses, tends to reject most temperature correlations, and instead compares the distributions of the rarer species with the distribution of water masses characterized by the plankton community represented by the chaetognath *Sagitta elegans*.

As one reads the accounts of individual species one gains the impression that the author considers that the presence of "*Sagitta elegans* water" is the predominant environmental factor governing the distribution of echinoderms. Even if the experiments on biological factors in such water are considered conclusive, it is difficult to believe that they can have much influence on non-pelagic larvae or on the adults themselves. Many inconsistencies in distribution in the North Sea would be more intelligible if other environmental factors were considered. Not only temperature but also depth of water, type of deposit and continuity of faunas must be of more direct importance to most species of echinoderms than hypothetical factors associated with water masses. In conclusion, the possibly subjective interpretation must not be allowed to detract from the general importance of this paper, which will form the basis for much future discussion, and zoogeographers will be grateful to Dr. Ursin for his careful compilation of the distributional records.

A. J. Southward

WESTFIELD COLLEGE (UNIVERSITY OF LONDON)

NEW FACULTY OF SCIENCE

SINCE its return to London after the break of the war years, Westfield College (University of London) has been a College in the Faculty of Arts only, except for mathematicians, who have taken either the B.Sc. (Special) or B.A. degree. Previously, the College had a small, but flourishing, Department of Botany, but this was relinquished in 1950 as a result of the difficulties encountered in running one science department in isolation.

In November 1955 the College Council decided to press for the re-introduction of science, but on a wider basis, and the advice of Sir Lawrence Bragg and other eminent scientists was sought and most kindly given. The reasons for the decision probably need no advocacy, but are summed up as follows: "We are convinced that the College would gain immeasurably by the re-introduction of Science: past experience has shown that the contact between students of Science and students of the Arts, living and working side by side, is of the greatest benefit to both, in ways difficult to analyse but none the less real". The original plan was to establish a Faculty of Science "comprising Special Honours Departments of Chemistry, Physics, Botany and Mathematics (already in being), with in addition a two-year Zoology course" (afterwards included as a special honours department) and that these departments should "at the same time cover the requirements of the B.Sc. General Honours Degree". The shortage of science teachers in the schools was kept in view, and it was thought that "there might well be a temporary paucity of properly qualified candidates for Special Honours courses (but) . . . that to have the stimulus of Special Honours Departments is the right policy in the long view". A Faculty of approximately two hundred students was envisaged, though this was increased later in the light of advice from the University. The College possessed its old botany laboratories, equipment and materials, which had been retained, and the botany library, where periodicals and series had been kept up to date. It also had a site for extensions.

In June 1956 a small body of experts appointed by the University went to examine the building plans and confer about staffing and accommodation. Their opinion was that the site proposed was too restricted, and an alternative site allowing for more research facilities as well as possible expansion had to be found. It was also stated by the University when examining the estimates that the original plan was too modest and that if the plan were to be given ultimate sanction the College should think in terms of a building costing about half a million pounds, and also that the building must be ready to accept students in October 1961. The building plan was modified more than once to accord with London County Council requirements and finally it became evident that to obtain a site of sufficient dimensions one of the College residences would have to be demolished.

In all these negotiations the College was helped by the criticism and advice of the inspectors appointed by the University, some of whom afterwards became 'science advisers' to the College and to whom it is deeply indebted, notably Prof. H. T. Flint (then Hildred Carlile professor of physics at Bedford College), Prof. W. S. Bullough, professor of zoology at Birkbeck College, and the late Prof. W. Wardlaw, professor of chemistry at Birkbeck College. After his death in December 1958 his successor, Prof. W. G. Overend, consented to act as adviser in chemistry. In botany no special adviser was sought, since there were some past members of the College who had specialized knowledge. The architects responsible for the laboratories are Messrs. Verner Rees, Laurence and Mitchell. The actual demolition of the property to clear the site began in May 1959, and the official laying of the foundation stone of the new building was performed by Sir John Cockcroft in May 1960. Meanwhile, the intellectual foundations have been laid in the present academic year by the appointment of the first professors and by the recognition by the University of the College as a School in the Faculty of Science.

The appointments are as follows:

PHYSICS. *Prof. E. H. Bellamy.* Dr. Bellamy was educated at Quarry Bank High School, Liverpool, and proceeded to King's College, Cambridge, as a State Scholar in 1941. He obtained a first class in the Natural Sciences Tripos in 1943 and then worked for three years as a scientist in the Road Research Laboratory, Department of Scientific and Industrial Research and at British Insulated Callender's Cables, Ltd. Returning to Cambridge after the War, Dr. Bellamy completed a double-first in the Natural Sciences Tripos in 1948 and thereafter did research work in the Cavendish Laboratory for the Ph.D. degree, which he obtained in 1951. During this latter period Dr. Bellamy made the first measurements in Europe of nuclear spins and magnetic moments using atomic beam techniques. He was appointed to a lectureship at the University of Glasgow in 1951 and rendered valuable help in the development of experimental techniques for utilizing the beam of the 300-MeV. synchrotron which operates there. During the past five years, Dr. Bellamy has made many contributions to our knowledge of photoproduction of π-mesons and has very successfully supervised young research students who have collaborated with him in these and other experimental studies. He is at present on short leave of absence to carry out an experiment on the 1,000-MeV. synchrotron at Frascati. Dr. Bellamy has also taken a full share in departmental teaching and social activities at Glasgow, and has been very popular with undergraduate students.

CHEMISTRY. *Prof. W. Klyne.* Dr. Klyne was educated at Highgate School and New College, Oxford, where he read chemistry. Since then he has worked in

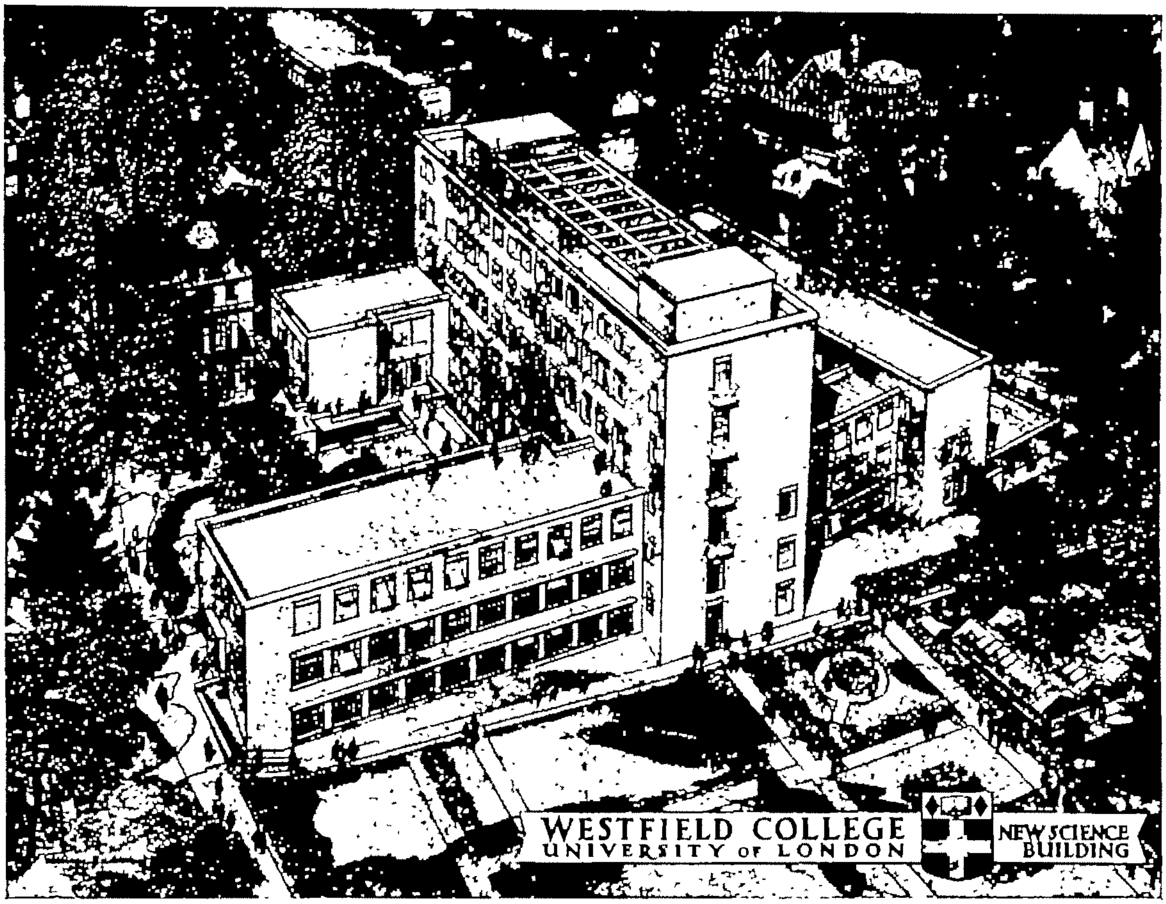

Fig. 1. Photograph of artist's drawing of the new Faculty of Science Building, Westfield College. (Artist: William Suddaby. Photographer: Sydney W. Newbery)

the Department of Medical Chemistry in the University of Edinburgh and in the Department of Medical Pathology at the Postgraduate Medical School of London, where he has been reader in biochemistry since 1952. Prof. Klyne has written "Practical Chemistry for Medical Students", which has been widely used. He is an expert and master of stereochemistry, particularly in regard to the biological steroids and the relation of optical rotation and rotary dispersion to chemical structure. His approach to the subject ranges from biochemistry and organic chemistry to the theoretical aspects of the shape of molecules. His interest in scientific method and his past experience should ensure success for this new department of chemistry.

Botany. *Prof. G. E. Fogg.* Dr. Fogg needs no introduction to most biologists for he is well known as a secretary of the Society for Experimental Biology, as one of the co-editors of the Penguin "New Biology" series and as the author of the book "Metabolism of Algae". Dr. Fogg took his degree in botany at Queen Mary College, London, and went to Cambridge to do his postgraduate research. Since 1945 he has been an invaluable and distinguished member, first as lecturer and now as reader, of the Botany Department in University College, London. Dr. Fogg's research work on the metabolism of algae, involving as it does the growing of algae in pure culture and the use of modern techniques, has been distinguished for its skilful, experimental approach. More recently, he has extended this work to the study of the physiology of phytoplankton in fresh water and the sea. Around this new and expanding field of research, Dr. Fogg will be able to build a sound teaching department at Westfield College.

Zoology. *Prof. J. E. Webb.* Dr. Webb returns to Great Britain after a period of eleven years as head of the Department of Zoology in the University College of Ibadan, Nigeria. After graduating from Birkbeck College, London, he held for a short time a post as research entomologist before taking up a lectureship at Aberdeen. His many publications during this period include important contributions on the morphology and ventilation mechanisms of insect tracheae. The creation and development of a flourishing department at Ibadan and of an attractive and well-stocked zoological garden are a tribute to his energy and powers as an organizer. Under his leadership and guidance the Department has acquired a well-deserved reputation for good teaching and research. Many of his students have graduated with honours degrees under the scheme of special relationship with the University of London and have taken up teaching and research posts in Nigeria; two of them are on the staff of the Department. Prof. Webb, besides playing an active part in the affairs of the University College, as dean of the Faculty of Science and member of the College Council, has established himself as an authority on the systematics of the cephalochordates, and his most recently published work, in the *Philosophical Transactions of the Royal*

Society, includes studies on the geomorphology and ecology of the lagoon systems of Lagos and the adjacent coastline.

All these professors will hold office from October 1960, in order to be responsible for final preparations and for appointment of staff before the first intake of students in October 1961. They will select their first students in November 1960, and the schools have already been circularized.

MATHEMATICS. *Prof. E. H. Sondheimer*. The Mathematics Department is in a different position, since the College never ceased to accept students for the B.Sc. special degree. The Department (about fifty students) is at present directed by a reader, but it had long been decided to apply for a chair in due course. The introduction of the Faculty of Science made it desirable that the change should take place now and the first professor of mathematics is Dr. E. H. Sondheimer. He is, at present, University reader in applied mathematics in Queen Mary College, London, a post which he has held since 1954. Prior to this, he held a lectureship in mathematics in the Imperial College of Science and Technology, to which he was appointed in 1951. This was, in fact, his first teaching post. Dr. Sondheimer has had a varied and interesting career; after taking the Natural Science Tripos at Cambridge in 1943, he joined a small team carrying out war work on experimental studies of the properties of transformer sheet steels. At the end of the War he began research work in the electron theory of metals at Cambridge, to which subject he has made several important contributions. He was awarded a Smith Prize in 1947 and in 1948 elected to a research fellowship at Trinity College which he took up in 1950. In the intervening years he worked first under Prof. N. F. Mott at Bristol and later was in the United States, working with Prof. Slater at the Massachusetts Institute of Technology. Dr. Sondheimer is best known for his work on the anomalous skin effect in metals, which was done in collaboration with G. E. H. Reuter. Later extension of this work paved the way for Pippard's pioneering work on determination of the Fermi surface in metals. Dr. Sondheimer's other important contributions include the first successful solution of the Bloch integral equation, the application of variational methods to conduction phenomena in polar semi-conductors, and a general proof of the validity of Kelvin relations occurring in the theory of phonon drag.

CONTROL OF PRE-NATAL GROWTH IN MAMMALS

By DR. ANNE McLAREN

Agricultural Research Council Unit of Animal Genetics,
Institute of Animal Genetics, King's Buildings, Edinburgh 9

AND

DR. DONALD MICHIE

Department of Surgical Science, University New
Buildings, Edinburgh 8

TO some extent every mammal decides for itself what size it will attain, in the sense that its own genetic constitution sets limits to its growth. However much we feed a Shetland foal it will not grow as large as a Shire horse. But there is evidence that these intrinsic factors exert their main effects in post-natal life, and that pre-natal growth is largely controlled by the intra-uterine environment.

An early indication of this was Walton and Hammond's[1] remarkable demonstration that the new-born foals of Shire mares crossed to Shetland stallions were almost as large as pure Shire new-borns, while the offspring of the reciprocal cross were as small as new-born Shetlands. The presumption was that the uterine environment was responsible, although the possibility of a cytoplasmic effect was not excluded.

Subsequent work with man[2], cows[3], rabbits[4], sheep[5] and mice[6] has confirmed the existence of large maternal effects upon weight at birth, and in the last three cases it has been shown by means of egg transfer that the effects are indeed mainly uterine.

Equally clear evidence of the importance of factors extrinsic to the embryo is the well-known effect of litter-size on weight at birth in polytocous species. According to Healy, McLaren and Michie[7], when the range of litter sizes in mice is artificially increased, differences of more than two-fold in the mean weights of full-term foetuses can be obtained. The classical explanation of such effects is that there is a limited pool of nutriment in the maternal blood for which the foetuses compete[8]. As each draws its ration, so much the less remains for the others.

In this article we review evidence suggesting that this explanation is incomplete, and that most effects of litter size on foetal growth can be given a more plausible explanation in the elementary principles of hydrodynamics to which the flow of blood to the placenta is subject.

In the case of species with a bicornuate uterus, the theory of a limited pool of nutriment predicts that the growth of a foetus in one uterine horn will be just as much retarded by the presence of litter-mates in the other horn as in the same horn. But Eckstein, McKeown and Record's[9] study of guinea pig pregnancies showed this not to be the case. They found that the number of embryos in the same horn was more important than the number in the opposite horn in determining both foetal weight and the weight of the placenta, on which foetal growth in large measure depends. The picture which emerges from their results can be summarized as in Fig. 1.

With regard to the possible mechanism underlying this scheme, Eckstein *et al.* pointed out that since resistance to blood flow through the placenta is low, the pressure at which blood is supplied to each placenta may be inversely related to the number of placentae supplied by the uterine artery on the same side. It can be supposed that the supply of blood, and of its dissolved nutrients, conditions the rate of

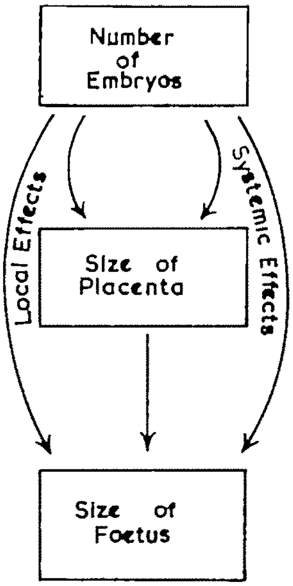

Fig. 1. Scheme showing the pathways by which the number of implanted embryos can affect fœtal growth, as suggested by the work of Eckstein, McKeown and Record (ref. 9). Reproduced by permission of the Royal Society

fœtal growth, both directly, and also indirectly by determining in the earlier part of pregnancy the size attained by the placenta. The local effect of the number of embryos is in this way neatly accounted for, and the authors pointed out that in order to accommodate the residual non-local, or systemic, effect it is only necessary to postulate that changes of blood pressure on one side are to some degree transmitted to the contralateral uterine artery.

In the course of an experiment on the induction of superpregnancy in mice[10], large numbers of full-term fœtuses were weighed, with results[7,11,12] which support this attractive hypothesis. The existence of substantial local effects on fœtal growth was confirmed. The effects, both local and systemic, of embryos surviving into late pregnancy were paralleled by effects of almost equal magnitude exerted by embryos dying in mid-pregnancy. These effects can scarcely be accommodated by the nutritional pool theory, since the nutritional demands of such embryos must be extremely small. But on the hæmodynamic theory the result is reasonable, for by surviving long enough to form a placenta, such an embryo will limit the size attained by the placentæ of other embryos and hence will limit their subsequent growth.

In addition, an extreme test of the theory of competition for a limited nutritional pool was afforded by the induction of superpregnancy in sexually immature females. These animals, as might be expected, show marked signs of nutritional stress[12], yet their full-term fœtuses were not significantly lighter than those of a parallel series of superpregnant adults (*see* Fig. 2).

It seems sufficiently clear that the limited pool theory is inadequate. At the same time, other features of the observations conformed rather well with expectation on the basis of the hæmodynamic theory of Eckstein *et al.*

The supply of blood to each uterine horn of the mouse is derived from offshoots of a main loop artery fed from the abdominal aorta at the top and from the iliac artery at the bottom. In such a system the pressure of blood must be highest in the top and bottom offshoots, decreasing in the offshoots towards the middle. We might consequently expect the larger fœtuses to be at either end of the horn and the smaller ones to be in the middle. This is precisely what has been found[11], with a particular exception which, however, helps to establish the rule. The exception is the topmost fœtus of all, which, especially in crowded horns, is usually supplied by one limb of a bifurcated offshoot of which the other limb supplies the ovary. This fœtus, especially in crowded horns, is on average smaller than its neighbour[7].

The factors controlling fœtal growth which have so far been discussed are summarized diagrammatically in Fig. 3, which is based on the suggested relationship between fœtal growth and uterine blood flow.

Another case of bifurcation relates to the phenomenon of placental fusion[13], where the fœtuses involved also have to divide between them the supply from a single offshoot. Here again, retardation of growth is found. On the other hand, in fused pairs of which one member has died in mid-pregnancy, the survivor presumably enjoys the full output of one arterial offshoot, a circumstance which tallies with the finding that such fœtuses are not significantly retarded relative to their non-fused hornmates.

In general, the hæmodynamic theory seems to account well enough for variations in fœtal growth other than those due to genetic differences between pregnant females.

There is, however, an important exception to which Hammond's concept of limitation of nutrients has a clear application. In some species the young are born at a relatively advanced stage of growth and development, so that their terminal demands upon maternal nutrition are large. One such species is the sheep, in which Wallace[14] has shown that the weight of the young at term, particularly in twin pregnancies, can be drastically altered by varying the plane of maternal

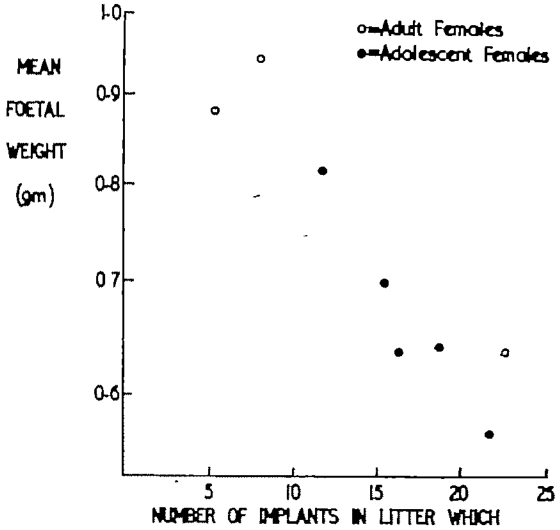

Fig. 2. Mean weights (scaled logarithmically) of 18-day live mouse fœtuses plotted against the mean number of implants surviving beyond day 10. Each point is based on 5–7 superpregnant females. In contrast to the large effect of litter size, effects of maternal age are small or non-existent

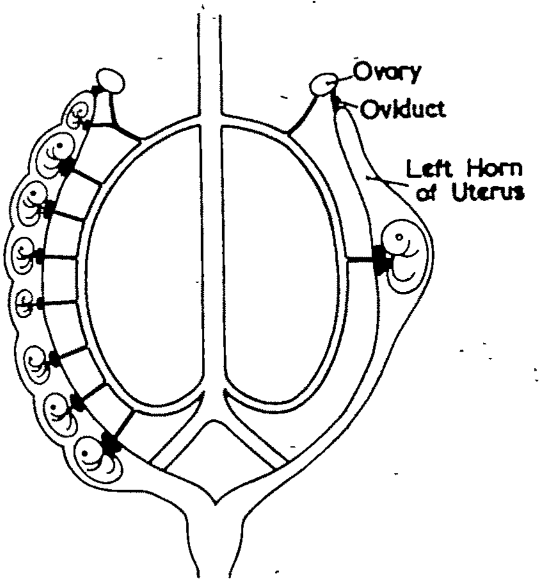

Fig. 3. Diagrammatic summary of various factors controlling fœtal growth. The one-to-one relation between fœtuses and vascular offshoots is an over-simplification. Note retardation of growth caused by (*a*) more fœtuses in the horn, (*b*) position of top fœtus in the horn, and (*c*) increasing distance from the ends of the horn. The correlation between placental and fœtal sizes is also indicated

nutrition during the last 6 of the 21 weeks of pregnancy. No effect could be obtained at earlier stages.

Such results do not, of course, exclude the simultaneous participation of the hæmodynamic mechanisms discussed earlier. That these mechanisms may have application to the human species is suggested by the finding that mothers who smoke give birth to babies weighing, on average, 6 oz. (170 gm.) less than the babies of non-smokers[15]. Since smoking causes peripheral vasoconstriction of about half an hour's duration, it is quite possible that repetition many times a day might restrict the placental circulation sufficiently to affect the growth of the fœtus. It remains to be seen whether such differences in weight at birth as that between the Shire–Shetlands and Shetland–Shires of Hammond and Walton can be accounted for in terms of vascular architecture and the mechanics of fluid flow.

NATURE OF THE HÆM-BINDING GROUPS IN NATIVE AND DENATURED HÆMOGLOBIN AND MYOGLOBIN

By Dr. JOAN KEILIN
School of Veterinary Medicine, University of Cambridge

HÆMOGLOBIN is very widely but somewhat irregularly distributed in Nature[1,2]. It is found in all vertebrates with the exception of certain bloodless fish living in the antarctic seas, and in many species of different phyla of invertebrates. Its presence has also been demonstrated in a few ciliates among the Protozoa, in certain strains of yeasts and moulds and in the root nodules of leguminous plants.

Although the hæmoglobins, irrespective of their origin, have the same fundamental property of reversible oxygenation and have the same hæm nucleus as their prosthetic group, they differ greatly in their biological, chemical and physical properties[3] such as their affinity for oxygen and its dependence on *p*H, their affinity for carbon monoxide, molecular weight, solubility, ease of crystallization and crystalline form, the amino-acid composition of the protein, the isoelectric point, electrophoretic behaviour, ease of denaturation and immunological properties. Different hæmoglobins have been found within the same species of animals and even in the same individual, and extensive investigations are now being carried out on different genetically controlled hæmoglobins in man, cattle, sheep and other animals[4–6].

One may therefore ask what is the structural peculiarity which must be common to the proteins of all the hæmoglobins, irrespective of their origin and the great diversity of their properties, that imparts to the identical hæm nucleus (protohæm) the remarkable and not easily imitable property of combining reversibly with molecular oxygen, while at the same time protecting its divalent iron from oxidation. This is one of the most important problems which faces all those engaged in the study of hæmoglobin. That this fundamental property depends on the integrity of the protein moiety is clearly shown by the fact that the slightest disturbance in its structure is immediately reflected in the ability of its divalent iron to combine reversibly with molecular oxygen, while denaturation of the protein results in the complete loss of the property of oxygenation. In this respect hæmoglobin is, if anything, more fragile than a number of enzymes.

Although in hæmoglobin, as in other hæmoproteins, it is the entire protein portion of the molecule that influences the properties of the hæm, the first and most convenient approach to the study of this problem is to determine the nature of the groups which link the protein to the hæm iron; these will be referred to as the hæm-binding groups of the protein.

The main object of this article is to evaluate the different views which have recently been put forward as to the nature of the hæm-binding groups and to introduce some new criteria which can be applied to their study, not only in mammalian hæmoglobin and myoglobin but also—a point of great importance—in hæmoglobins of different origins, which differ widely in the amino-acid compositions of their proteins.

Nature of the Group linking the Hæm Iron to the Protein

In considering the nature of the hæm-binding group of globin, the following four possibilities have so far been suggested: (1) the imidazole group of histidine; (2) the carboxyl groups of aspartic and glutamic acids, (3) the sulphydryl group of cysteine; and (4) no specific group.

(1) *The imidazole group of histidine.* The most widely held view is that the iron-linked group of globin is the imidazole ring of histidine. This was at first suggested mainly because mammalian hæmoglobin is rich in this amino-acid; and later this view received strong support from an extensive study of certain physico-chemical properties of hæmoglobin which we owe primarily to Wyman[6] and to Coryell and Pauling[7]. The imidazole ring of histidine as the hæm-linking group has already been discussed on several occasions[4,8,9] and will be dealt with farther on.

(2) *Carboxyl groups.* It was recently suggested by O'Hagan[10] that the hæm iron is bound to a carboxyl group of globin, since the pH stability curves of methæmoglobin obtained by the oxidation of hæmoglobin, or by its reconstitution from native globin and hæmatin, show ionizing groups with pK 4·7. This value lies closer to the pK of the carboxyl groups of aspartic and glutamic acids than to that of the imidazole group of histidine (pK 5·3). This view was also supported by Haurowitz[11].

(3) *Sulphydryl group.* The possibility that the hæm iron is linked to globin through a sulphydryl group of cysteine was at first suggested by Haurowitz[12], who later abandoned this view when myoglobin was found to be free of cysteine[13]. The idea was, however, recently revived by Riggs[14,15], who found that the magnitude of the Bohr effect in mammalian hæmoglobins was proportional to the number of sulphydryl groups which could be titrated by mercuric ions and that the hæm–hæm interaction, which is responsible for the S-shaped oxygen dissociation curve, is abolished when the sulphydryl groups are blocked by p-chloromercuribenzoate. He concluded that the two physiologically important properties of hæmoglobin, the Bohr effect and the S-shaped dissociation curve, are both mediated by sulphydryl groups which link the hæm iron to the globin. He also suggested that much of the physico-chemical evidence presented in favour of the imidazole ring as the hæm-linking group could equally well apply to the sulphydryl group.

(4) *No specific group.* Having discarded the possibility of the sulphydryl nature of the hæm-binding group, Haurowitz and Hardin[16] suggested "that the common feature of all globins is a complementary 'anti-heme' pattern which permits them to approach very closely the flat heme structure", so that the "hemoglobin structure would be maintained by London – van der Waals forces between the molecular surfaces of the heme and the anti-heme pattern of the globin". Since this view does not refer to the protein groups specifically linked to the iron, it may be considered as complementary to each of the previous hypotheses.

For the proper evaluation of these views on the possible nature of the hæm-linked groups in hæmoglobin, it is necessary to consider the reactions of free hæm and hæmatin with different substances, and to determine the requirements for the formation with some of them of the corresponding hæmochromogen and parahæmatin compounds.

Formation of Hæmochromogens by Hæm with Nitrogenous Bases

Hæm, the prosthetic group of hæmoglobin, is a flat molecule consisting of four pyrrol nuclei joined by methene bridges to form a porphyrin ring, with a divalent iron atom occupying the centre. Of the six co-ordination valencies of the iron, four lie in one plane and link it to the nitrogen atoms of the pyrrol nuclei, whereas the remaining two valencies, the fifth and sixth, one on each side of the flat hæm molecule, link it to molecules of water. An alkaline solution of hæm shows two diffuse absorption bands at about 580 and 560 mμ. The addition of pyridine to the hæm solution at once gives a pyridine hæmochromogen compound with two strong absorption bands in the visible region; α at 557 and β at 525 mμ ($\alpha > \beta$). Analogous hæmochromogens can be obtained with a great variety of nitrogenous bases[17,18] such as piperidine, pyrrolidine, nicotine, various amines, imidazole, ammonia, hydrazine hydrate and others. In all hæmochromogens the hæm iron is linked by covalent bonds in positions 5 and 6 to two molecules of the base[19], which replace the molecules of water.

Cyanide, unlike other nitrogenous substances, forms two distinct compounds with hæm: monocyan- and dicyan-hæm. While the general pattern of the absorption bands of monocyan-hæm resembles that of a hæmochromogen, the pattern of the dicyan-hæm spectrum differs from it and is very similar to that of the dihydroxy-hæm compound[20]. Monocyan-hæm has a strong affinity for nitrogenous bases; for example, with imidazole it forms a hybrid imidazole–cyanide hæmochromogen in which one of the two positions around the iron (fifth or sixth) is occupied by cyanide, the other by a molecule of imidazole. Such a hybrid hæmochromogen can also be obtained by treating an ordinary hæmochromogen with cyanide, which replaces one of the two molecules of the base linked with the hæm iron[21]. In this reaction the absorption bands in the visible region of the imidazole hæmochromogen are shifted to longer wavelengths, their positions in the imidazole cyanide hybrid hæmochromogen being α, 560 and β, 530 mμ, while the height (*EmM*) of the α band falls from 0·28–0·32 to about 0·17.

In order to find what chemical groupings in a substance determine its ability to combine with the hæm iron by covalent bonds in positions 5 and 6 to form a hæmochromogen, I have examined a great variety of substances with regard to their reactions with hæm (unpublished work). It was found that hæm formed no hæmochromogens with alcohols, aldehydes, carbohydrates, fatty acids or phenols. Only substances containing a free nitrogenous group (as has been shown earlier) combine with the hæm iron to give the corresponding hæmochromogen compounds. Since not all nitrogenous substances were found to have this property, it is of interest to record here some of the biologically important nitrogenous substances which formed no hæmochromogens with either protohæm or other hæms (hæmatohæm, deuterohæm, mesohæm, coprohæm and urohæm), although the experiments were carried out under a great variety of conditions. The list of nitrogenous substances which failed to give hæmochromogens included urea, guanidine, creatine, creatinine, pyrrol, indol, indolacetate, proline, purines such as adenine, guanine, hypoxanthine, xanthine, uric acid, caffeine, theophylline and theobromine, pyrimidines (cytosine and thymine), adenosine, nucleic acid and its derivatives, and flavine. It is interesting to note that of all the purines and pyrimidines tested, only the unsubstituted free bases, purine and pyrimidine, gave a hæmochromogen.

The divalent iron of hæmochromogens easily undergoes reversible oxidation to the tervalent iron of the corresponding parahæmatins, which have a diffuse absorption band at about 530 mμ with a shoulder at 558 mμ. In a similar way, the oxidation of a hybrid hæmochromogen gives the corresponding hybrid parahæmatin. The formation of this compound was discovered[22] in early work on the inhibition by cyanide of the oxidation of cysteine catalysed by pyridine hæmochromogen. It was shown by Drabkin[23] that this hybrid parahæmatin can be obtained by treating hæmatin with cyanide and pyridine in the ratio of 0·1 to 5,000.

The oxidation-reduction relationship:

$$\text{hæmochromogen} \rightleftharpoons \text{parahæmatin}$$

is analogous to those of:

$$\text{hæm} \rightleftharpoons \text{hæmatin and hæmoglobin} \rightleftharpoons \text{methæmoglobin}$$

Carboxy-hæm and Carboxy-hæmochromogen Compounds

On treating hæm with carbon monoxide, its colour turns from reddish brown to bright red and its very diffuse absorption bands at 580 and 560 mμ are replaced by two strong bands: α, 563, β, 533 mμ (α > β). In this reaction, of the two molecules of water co-ordinated with the divalent hæm iron in positions 5 and 6, only one is replaced by a molecule of carbon monoxide. Similarly, when a hæmochromogen is treated with carbon monoxide, one of the two molecules of the base is replaced by carbon monoxide, giving the corresponding carboxy-hæmochromogen[19] which, as was shown for the first time by Krebs[21], is sensitive to light.

The study of carbon monoxide derivatives is of great importance when considering certain reactions between hæm and proteins. In fact, as carboxy-hæm has a much greater affinity for nitrogenous substances than has free hæm, it was used as well as mono-cyan hæm for the final assessment of compounds as to their ability to combine with the iron of hæm. Moreover, since carboxy-hæm, like mono-cyan hæm, can combine with only one nitrogenous group, it can be used for the study of the reactivity of such a group when, owing to some spatial considerations, its co-ordination with the hæm iron is possible on only one side of the flat hæm molecule.

Hæmochromogen Formation by Amino-acids and Denatured Proteins

The reactions of free hæm with amino-acids and proteins are of special interest for the study of the hæm-binding groups in hæmoglobin as well as in other natural hæmoproteins. It can be demonstrated spectrophotometrically that neither free hæm nor free hæmatin combines with hæmoglobin or methæmoglobin respectively, which indicates that all the available hæm-binding groups of the native globin are already occupied. On mild denaturation, hæmoglobin forms globin hæmochromogen, which resembles the hæmochromogens given by hæm with different nitrogenous bases. When, however, free hæm is added to globin hæmochromogen, the absorption bands of the latter are greatly intensified, showing that denaturation of the globin increases its hæm-binding capacity at least six-fold. Although this property of globin, as well as of other proteins, was known for a long time[24–26], its full significance has not yet been properly appreciated. It was tacitly assumed that denaturation of proteins unmasks several potential hæm-binding groups belonging to different amino-acid residues, but early attempts to demonstrate the correctness of this assumption, by studying the reactions of hæm with free amino-acids, were very disappointing. According to Haurowitz[18], neither parahæmatin nor hæmochromogen could be obtained from hæmatin or hæm, respectively, treated with histidine, alanine, leucine, glycine, cysteine or glutathione, although it had been previously recorded[25] that glycine does give a hæmochromogen compound with hæm. Potentiometric titration[26] of 10^{-4} *M* hæmatin with sodium dithionite in the presence of histidine has shown that the oxido-reduction potential became constant only when the histidine added reached a concentration of 7×10^{-2} *M*. No attempt was made in this experiment to follow the reaction between hæm and histidine spectrophotometrically.

More recently spectrophotometric studies of the reactions between different hæms (protohæm, mesohæm, deuterohæm and urohæm) and amino-acids[18,27] revealed that, given the right conditions, typical hæmochromogen compounds were obtained with practically every amino-acid except proline, which shows that the α-amino group is a hæm-binding group common to all the amino-acids, provided that the hydrogens of the amino-group are not substituted; thus, while alanine gave a hæmochromogen, no hæmochromogen was obtained with N-monomethyl alanine or N-dimethyl alanine.

For the study of the reactions between hæm and proteins it was important to evaluate the hæm-binding properties of other potentially reacting groups of the amino-acids. Such evaluations were obtained from (1) the reactions of hæm with amino-acids in which the participation of the α-amino group was eliminated by being involved in a peptide linkage, or (2) the reactions of hæm with the potentially hæm-binding group either in the free state—for example, imidazole—or forming part of a compound free from other possible reacting groups—for example, the imidazole ring in pilocarpine.

The results of this work (unpublished), carried out with different hæms and their carbon monoxide derivatives, showed that only basic nitrogenous groups of amino-acids can combine with hæms or carboxy-hæms to give the corresponding hæmochromogens or their carboxy derivatives. This eliminates from the list of potential hæm-binding groups in denatured proteins the carboxylic side-chains of glutamic and aspartic acids, the benzene ring of tyrosine and phenylalanine and the sulphydryl group of cysteine. Of the nitrogenous basic groups such as the terminal α-amino group of different amino-acids, the ε-amino group of lysine, the imidazole group of histidine and the indole group of tryptophan, only the first three were definitely established as potential hæm-binding groups. The hæm-binding property of the imidazole group of histidine was supported by the great ease with which free imidazoles, or the imidazole ring of pilocarpine, or of urocanic acid and certain other compounds form parahæmatins and hæmochromogens (unpublished work; see also refs. 18, 31, 32). Strong evidence for the hæm-binding property of the ε-amino group of lysine was obtained from the study of polylysine, which was found to have ten times higher affinity for hæm than free lysine. On the other hand, the side-chains of tryptophan and arginine were eliminated as potential hæm-binding groups by the failure to obtain hæmochromogens with free indole and free guanidine, as well as with denatured salmine and clupeine, which can be considered as polyarginine peptides. It was also found that whereas pyrrolidine gave a good hæmochromogen, free proline failed to co-ordinate with the hæm iron.

The potential hæm-binding groups, which become unmasked by the denaturation of proteins, are therefore limited to the terminal α-amino groups, the ε-amino group of lysine and the imidazole group of histidine. The total number of such groups[13] in whale and horse myoglobins (molecular weight, 17,000) are 32 and 28 respectively, and in horse hæmoglobin (molecular weight, 68,000) there are 76–80, that is, about 19–20 per unit of molecular weight, 17,000. Since the hæm-binding capacity or 'hæm-number' of sperm whale myoglobin is 10 and that of horse hæmoglobin is 6 per unit of protein of molecular weight 17,000 (ref. 27), and since each hæm iron co-ordinates with two nitrogenous groups to form a hæmochromogen, about 62 per cent of all available hæm-binding groups in denatured myoglobin and hæmoglobin are involved in hæmochromogen formation.

The study of hæmochromogen formation by denatured proteins including the globins, which will be fully dealt with elsewhere, has led to the following conclusions:

(1) As the iron atom in hæmochromogens is co-ordinated with two nitrogenous groups lying one on each side of the flat hæm molecule and occupying the fifth and sixth co-ordination positions, the hæm in denatured protein hæmochromogen must lie within the folds of the protein. This is made possible by the unfolding of peptide chains which characterizes denaturation in proteins, that is, the breaking of the bonds of the tertiary structure of the hæmoglobin molecule.

(2) The two nitrogenous groups, one on each side of the protein fold, which are linked to the hæm iron are not necessarily of the same nature; for example, one may be an imidazole group and the other an ε-amino group of lysine, or even an α-amino end-group.

(3) Since two nitrogenous groups, one on each side of the fold, are required for the formation of a hæmochromogen, there must be a certain regularity in their distribution in order to assume a high 'hæm number' which may involve more than 50 per cent of all the potential hæm-binding groups of the protein.

(4) The 'hæm number' of a denatured protein must therefore depend on: (a) the number of free nitrogenous hæm-binding groups; (b) a certain regularity in their distribution; and (c) freedom from steric hindrance by neighbouring side-chains. In this respect consideration should be given to all side-chains not involved in hæm-binding; for example, SH or S—S groups, the guanidine group of arginine, the indole group of tryptophan, the benzene ring of tyrosine or phenyl-alanine, and the carboxylic groups of glutamic and aspartic acids.

Reversible Formation of Hæmochromogen by Native Hæmoglobin

The fact that the iron atoms of hæmoglobin and methæmoglobin are accessible to, and easily combine with, a great variety of ligands some of which, like nitrosobenzene and imidazole, are of an appreciable size, clearly shows that the hæm or hæmatin is well exposed and not buried deeply within the folds of the protein[33–35].

That the hæm is bound to the globin not only by its iron atom but also by its porphyrin ring is indicated by the marked effect that free native globin has on the absorption spectrum of an alkaline solution of free porphyrin, and by the competition of porphyrin and hæm for native globin in experiments on the reconstitution of hæmoglobin from its components[36]. The two carboxyl groups of hæm are probably linked to the guanidine groups of the arginine residues[37].

Since the hæms in hæmoglobin are not buried between the folds of the globin, their iron atoms are linked to the globin by only one iron-protein bond (co-ordination position 5) lying on one side of the flat hæm molecule; on the other side (position 6), the iron is bound to a molecule of water, the presence of which was shown by spectroscopic studies[38] of the effect of low temperatures on alkaline methæmoglobin, and of the effect of drying on hæmoglobin and methæmoglobin.

The molecule of water in position 6 can be replaced in hæmoglobin by oxygen, carbon monoxide, nitric oxide, cyanide, alkyl cyanides or nitrosobenzene, and in methæmoglobin by fluoride, azide, cyanide, sulphide, nitric oxide or imidazole. As under certain well-defined conditions the denaturation of hæmoglobin was found to be a reversible process (unpublished work and ref. 38), it is possible that in the globin hæmochromogen thus obtained one of the two bonds uniting the hæm iron to globin is the original iron-protein bond present in hæmoglobin. The persistence of the original iron-protein bonds of hæmoglobin during the reversible formation of globin hæmochromogen and parahæmatin can be demonstrated by the following experiments.

(1) *Drying of hæmoglobin.* It has been shown that, when hæmoglobin or myoglobin is thoroughly dried, its absorption spectrum is replaced by that of a hæmochromogen[39–41]. On the addition of water, this reverts to hæmoglobin which, in the presence of oxygen, undergoes oxygenation to oxyhæmoglobin. This reversible formation of a hæmochromogen on drying is due to the fact that the molecule of water linked to the iron atom in the sixth co-ordination position is removed and replaced by a nitrogenous group of the protein belonging to the same molecule of hæmoglobin.

(2) *Drying of methæmoglobin.* In a similar way, the drying of acid methæmoglobin converts it reversibly to a parahæmatin[41]. That fluoride and azide methæmoglobin are not changed by drying to a parahæmatin is not surprising, since the fluoride or azide which replaced the water molecule of the methæmoglobin prevents the hæm iron from co-ordinating in position 6 with a nitrogenous group of the globin, brought closer to the iron by drying. The

fact that the absorption spectra of hæmoglobin and methæmoglobin are easily replaced on drying by those of the hæmochromogen and parahæmatin spectra, respectively, suggests that either an imidazole group of histidine or, more likely, an ε-amino group of lysine, must lie in close proximity to the water molecule attached to the iron atom.

(3) *The reaction of methæmoglobin with cyanide.* On treating acid methæmoglobin with cyanide, its colour changes from brown to red and its absorption band at 630 mμ is replaced by a wide band at 540 mμ. Cyan-methæmoglobin, which is one of the oldest known methæmoglobin derivatives[41], was at one time wrongly considered as an irreversible compound because of the very high affinity of cyanide for the tervalent iron of the methæmoglobin. Spectroscopically, it shows a close resemblance to the hybrid cyan-pyridine or cyan-imidazole parahæmatins referred to earlier.

(4) *The reaction of hæmoglobin with cyanide.* Cyan-hæmoglobin can easily be obtained by reducing cyan-methæmoglobin with sodium dithionite[42–44]. While the cyan-hæmoglobin obtained in this way is very unstable and rapidly dissociates into hæmoglobin and cyanide, cyan-myoglobin is sufficiently stable for spectrophotometric studies. It has a characteristic absorption spectrum very similar to that of cyan-pyridine or cyan-imidazole–hybrid hæmochromogens, with two strong absorption bands: α, 562 and β, 535 mμ (α > β). Cyan-myoglobin can be described as cyan-native globin–hybrid hæmochromogen, and its formation requires a high concentration of cyanide at *p*H 9. A compound which is practically indistinguishable from cyan-methæmoglobin was obtained[45] by treating reduced peroxidase with cyanide at *p*H 8·5–9·3. An interesting point was the discovery that cyan-ferroperoxidase and, to a lesser degree, cyan-myoglobin, undergo reversible photodissociation, liberating ferroperoxidase and myoglobin respectively and cyanide[46].

The fact that in these experiments hæmochromogens and parahæmatins were reversibly obtained from hæmoglobin and methæmoglobin respectively, on replacing the water molecule bound to the hæm iron in position 6 by a suitable nitrogenous compound, indicates that in position 5 the hæm iron must be linked to a nitrogenous compound which is the original hæm-binding group of the hæmoglobin. Since this group is a potential hæmochromogen-forming compound, it can only be the imidazole ring of histidine, the ε-amino group of lysine or, less likely, an amino end-group. This eliminates from the list of potential hæm-binding groups the side-chains of all other amino-acid residues, and also dismisses the possibility that the hæm-binding group could originally have been one of the non-hæmochromogen-forming side-chains which was replaced by a hæmochromogen-forming group only when the water molecule in position 6 was exchanged for a suitable nitrogenous substance. In fact, such a process would imply a rapid and reversible displacement of the hæm molecule in relation to the globin; this could scarcely take place, considering (*a*) that hæm is bound to the globin not only by its iron atom but also by the propionate groups and by van der Waals forces between its surface and that of the globin[16], (*b*) that reversible hæmochromogen formation may take place under conditions precluding the denaturation of the hæmoglobin, and (*c*) that cyan-native globin hæmochromogen can be dissociated by light into cyanide and hæmoglobin.

Evidence for the Imidazole Ring of Histidine as the Hæm-binding Group of Globin

Although the hæmochromogen criterion reduces the number of potential hæm-binding groups in hæmoglobin to only three types of basic groups, the imidazole ring of histidine, the ε-amino group of lysine and a terminal α-amino group, it makes no discrimination between them.

Of the views as to the nature of the hæm-binding group which were discussed earlier, the hæmochromogen criterion provides evidence only in favour of the imidazole theory which, as was shown above, was also supported by physico-chemical evidence[6–9], and by the facts that the globins of hæmoglobin and myoglobin are very rich in histidine. It must, however, be remembered that the physico-chemical evidence is largely based on the assumption that the properties of the imidazole ring of histidine which is incorporated in the peptide chain of the globin are quantitatively identical with those of the imidazole ring of free histidine. That this may not necessarily be so is indicated by the fact that the affinities of amino-acids for hæm are greatly enhanced when they form part of a peptide chain[16]. It has also been shown that the formation of a carbamino compound by glycine was increased thirty-fold by condensing two glycine molecules to a dipeptide[9]. Some caution must therefore be exercised in describing certain properties of proteins in terms of what is known of the individual amino-acids.

In spite of certain objections raised against the idea of the imidazole nature of the hæm-binding group in mammalian hæmoglobins and myoglobins[10–12,14,15,33], this theory, unlike any of the others so far proposed, is strongly supported both by the hæmochromogen criteria and by our present knowledge of the properties of hæmoglobin and its derivatives.

More direct evidence in favour of the view that the imidazole group of histidine binds the hæm iron to the globin was obtained from the X-ray analysis of crystals of myoglobin[47]. Indeed, the great advances which were recently made by Perutz and his co-workers[48] in their studies on the structure of hæmoglobin and by Kendrew and his co-workers[47,49] on the structure of myoglobin enabled them to unravel the tertiary structure of a protein molecule for the first time. Their results were based on three-dimensional Fourier syntheses at 5·5 Å. resolution in the case of horse oxy- and met-hæmoglobin[48] and at 2·0 Å. resolution in the case of sperm whale metmyoglobin[47,49].

The myoglobin molecule was found by Kendrew *et al.*[49] to consist of a single polypeptide chain folded in a somewhat complex manner, the straight portions of the chain having the structure of cylindrical tubes consisting of α-helices. The high degree of resolution has also shown that an amino-acid residue strongly suggestive of histidine, arising from the peptide chain adjacent to the hæm disk, is directed towards the hæm iron atom, whereas on the other side of the disk, what appears to be the oxygen of a water molecule lies very close to the iron. The terminal amino-group lies well away from the hæm.

The molecule of horse hæmoglobin was found by Perutz *et al.*[48] to be composed of four sub-units, each consisting of a single peptide chain folded in a very similar manner to that of sperm whale myoglobin. The hæm of each sub-unit is located in a pocket of the folded peptide chain, the four pockets being com-

Table 1. AMINO-ACID CONTENTS, ISOELECTRIC POINTS (I.P.) AND MOLECULAR WEIGHTS (MOL. WT.) OF SOME OXYGEN CARRIERS

Hæmoprotein oxygen carrier	Grams of amino-acid per 100 gm. protein*						I.P.	Mol. wt.
	Hist.	Lys.	Arg.	Trypt.	Tyr.	Cyst.		
Myoglobins								
Sperm whale (ref. 13)	11·12	15·90	2·24	2·00	2·12	0	6 78	17,000

* The amino-acids selected are limited to those which have been determined in certain invertebrates (ref. 51). In the cases of mammalian hæmoglobin and myoglobin (ref. 13) and *Aplysia* myoglobin (ref. 50), the complete balance sheet is available.

Abbreviations: Hist., histidine; Lys., lysine; Arg., arginine; Trypt., tryptophan; Tyr., tyrosine; Cyst., cysteine.

pletely independent of each other, the iron atoms of the closest pair being 25 Å. apart. The hæm iron on the side where it is linked with a water molecule, both in myoglobin and in hæmoglobin, is freely accessible to ligands of a large size[43] including *p*-iodophenylhydroxylamine[44].

The finding that the molecule of horse hæmoglobin consists of four sub-units each with a structural configuration closely resembling that of sperm whale myoglobin is very interesting and unexpected, considering that the amino-acid compositions of these two hæmoproteins show marked quantitative differences in the case of practically every amino-acid residue[13]. Some of these differences are shown in Table 1.

It was suggested by Perutz *et al.*[45] that "probably the chain, once it is synthesized and provided with a hæm group around which it can coil, takes up this configuration spontaneously, as the only one which satisfies the stereochemical requirements of its amino-acid sequence". This suggestion has direct bearing on the problem of the susceptibility of hæmoglobin to denaturation, which consists primarily in the breaking of bonds leading to the opening or uncoiling of the tertiary structure. Of special importance in this respect are the observations on the reversibility of denaturation in hæmoglobin[46]. It is also known that globin separated from hæm is very unstable, and that the susceptibility of hæmoglobin to denaturation is also affected by the nature of the ligands occupying co-ordination position 6 and by the nature of the bonds which link the hæm iron to surrounding atoms. Thus oxyhæmoglobin is much more resistant than methæmoglobin to denaturation by strong alkali or chloroform. Finally, hæmoglobin is more susceptible to irreversible denaturation than myoglobin. This may be due to the close proximity of the four sub-units in hæmoglobin which, in the partly uncoiled state, may interfere with each other in the proper recoiling of the peptide chain.

Whether or not the structural configuration of the myoglobin molecule is of general significance will be determined only by the study of invertebrate hæmoglobins and myoglobins, the amino-acid balance sheets of which show very great differences from those of the mammalian hæmoproteins[13,50,51] (Table 1). The myoglobin of the marine mollusc *Aplysia* is of special interest in this respect. *Aplysia* myoglobin (molecular weight 18,000), which has been obtained in a pure crystalline state, contains only one histidine residue per molecule, and it differs from mammalian myoglobins and hæmoglobins in the content of all the other amino-acid residues[50]. Considering that, apart from *Aplysia* myoglobin, investigations have been carried out on the hæmoglobins of only very few invertebrates and on material which was incompletely purified and scarcely sufficient in quantity for accurate analysis by the methods then used, it is possible that further work may reveal the existence of a hæmoglobin devoid of histidine. That histidine is not a universally distributed amino-acid is shown by its absence from the proteins of certain strains of viruses[52]. The hæmochromogen criterion has, however, shown that in a hæmoprotein deficient or completely free of histidine, the hæm-binding role of the imidazole ring could be taken over by the ε-amino group of lysine or even by a terminal α-amino group.

Indeed, it is only the study of hæmoglobins and myoglobins of different origins, which show the greatest diversity in their amino-acid compositions and in their physical and chemical properties, that will reveal the nature of the structural peculiarity common to all of them (but not to other hæmoproteins which only undergo oxido-reduction) that confers on the divalent iron of the hæm the property of combining reversibly with molecular oxygen without undergoing oxidation.

I am indebted to the Wellcome Trust for a research grant, to Dr. J. C. Kendrew for crystalline sperm whale myoglobin, and to Dr. C. H. Bamford and Dr. W. E. Hanby for samples of polylysine.

NEWS and VIEWS

Physiology at University College, London: Prof. A. F. Huxley

MR. A. F. HUXLEY, who was recently appointed to succeed Sir Lindor Brown (*Nature*, 185, 733; 1960) as Jodrell professor of physiology at University College, London, is well known internationally for his very distinguished research record. Among his contributions may be mentioned the important part he played in elucidating the mechanism of the nerve impulse and in proving the 'saltatory' nature of propagation in myelinated axons. More recently, he turned his attention to the microscopic structure of muscle fibres and was able to clarify greatly the sequence of the structural changes which occur in striated muscle during activity. Throughout his experimental work, he has tackled difficulties with a remarkable technical ingenuity and mathematical skill, developing important new instruments as well as theories as he went along. A. F. Huxley started at Cambridge and Plymouth, in collaboration with Prof. A. L. Hodgkin, a partnership which proved extremely fruitful and continued for many years. During the Second World War, Huxley was engaged in operational research, first with Anti-Aircraft Command and later with the Admiralty. In 1941, he became a Fellow of Trinity College; his most recent Cambridge appointment was to a readership at the Physiological Laboratory. He was elected to the fellowship of the Royal Society in 1955. Although Huxley's research work is highly specialized, his scientific interests cover an unusually wide range, and many physiologists feel indebted to him for the help they received during the period of his editorship of the *Journal of Physiology*. Those who visit the meetings of the Physiological Society regularly are well aware of Prof. Huxley's ability to penetrate scientific problems of a diverse nature. No doubt, in his new appointment, he will find plenty of opportunities of applying this gift.

The Overseas Civil Service

IN an adjournment debate on the Overseas Civil Service on July 11, Mr. B. R. Braine, Mr. J. Callaghan, and Mr. J. D. Tilney pressed the claims of the Overseas Civil Service. Mr. Julian Amery, Under-Secretary of State for the Colonies, who replied for the Government, said that the strength of their plea was fully justified by the importance of the subject and the urgency of the problem. He agreed that strong, efficient and honest administration had been Britain's greatest contribution to the development of the colonies and that one of our main tasks is to leave a strong local administrative service. This is partly a matter of establishing proper principles governing the local administrative services, of taking them out of politics, and of making appointments the responsibility of public service commissions. It is also a matter of retaining the services of ex-patriates for many years to come, and particularly of discovering ways and means of encouraging them to stay and go on serving now that the Secretary of State, as power is transferred, can no longer offer assurance of a career structure and promotion prospects or guarantee jobs in Britain. There must instead be special inducements to serve, and special compensation for loss of office, if and when it comes. At present there are 15,000 pensionable members of the Overseas Service, including 7,000 in East Africa, 1,500 in Nyasaland and Rhodesia, and 2,000 in West Africa, and in addition more than 10,000 are on contract. It is our duty, he said, as well as our interest, to see that, as these territories move to independence, they have an administrative structure which will enable them to maintain stability and to achieve some economic and social expansion. Mr. Amery said he could not make a statement that night, but he assured the House that the Secretary of State for the Colonies regards the problems raised as of the highest importance and calling for urgent solutions.

British and Foreign School Society and Borough Road College

THE Nuffield Foundation has given £50,000 to the Borough Road College, Isleworth, for a new science block which will house mathematics, biology, chemistry and physics in one building. It will be known as the Nuffield Science Building. This independent College has a long tradition of producing teachers of mathematics and science, and the Foundation has made the grant to enable it to increase the number of specialist teachers of these subjects. Borough Road College belongs to the British and Foreign School Society, which is contributing £75,000 towards the general expansion of the College. With the aid of a capital grant from the Ministry of Education, it will be able to raise the number of students from 320 to 500. The College is one of the oldest teacher-training colleges in the world, and recently celebrated its 150th anniversary.

Science and the Public

IN his foundation oration, "The Diffusion of Knowledge", at Goldsmiths' College, University of

London, on March 17, Dr. Michael Grant, president and vice-chancellor of the Queen's University of Belfast, discussed particularly the extraordinarily increasing activity and problem of making specialized knowledge available to the non-specialized adult public, and especially—since his subject was the diffusion of knowledge—of the printed word rather than the use of television or sound-radio (Pp. 15. London: Goldsmiths' College, 1960). The amount of actual knowledge imprinted on the adult general public by these media remains infinitesimal in comparison with what is gathered from printed books; and Dr. Grant directed attention to the fact that commercial advertisers still spend only 13 per cent of their funds on television and 47 per cent on the Press. The sale of informative paper-backed books, of which first editions of as many as 50,000 might be printed and sold, was further evidence of the existence of a demand for popular knowledge.

Discussing the problems involved in popularization, Dr. Grant referred to the difficulty of simplification but emphasized that good popularization could create the atmosphere for good scholarship, in which before long important new research could arise: diffusion and stimulus could go together. There were also problems of vocabulary and presentation as well as of scholarship, nor was it possible to ignore entirely pronouncements on moral or even social values. Even a smattering of reasonably accurate knowledge, however, would make the non-specialized adult population much less likely to become credulous victims of all the nonsense of which people try to convince them, and the spreading of knowledge by popularization was highly relevant to the problem summed up by Sir Charles Snow as that of the two cultures. That problem could not be left entirely to the universities, though he thought they should study deliberately how to produce the habit of mind which will make its students want, both before and after graduation, to take an open-minded interest in at least something worth while outside their own careers. In conclusion, he appealed to his hearers generally to participate themselves in this extremely difficult, heavily criticized but fascinating task of popularizing knowledge, which was worth doing and had to be done, and was more likely to be done successfully by teachers than by most other people.

New C.S.I.R.O. Sugar Research Laboratory

It is announced that a new Sugar Research Laboratory will be set up by the Commonwealth Scientific and Industrial Research Organization, to form part of the Organization's Chemical Research Laboratories in Melbourne. The decision to establish the Laboratory has come after considerable discussion with representatives of the sugar industry, which is anxious to find new uses for the present surplus in Australian production. The surplus corresponds to about a million tons of sugar cane per year. Australia's biggest sugar producer, the Colonial Sugar Refining Co., Ltd., has agreed to contribute £2,500 per annum towards the running costs of the Laboratory. Dr. H. H. Hatt, previously officer-in-charge of the Organization's Organic Chemistry Section, has been appointed leader of research in the new unit.

The Output of Scientists in Scotland : 1600–1950

In a paper, "The Output of Scientists in Scotland, 1600–1950", published in *The Eugenics Review*, July 1960, R. H. S. Robertson advances evidence that from the beginning of the seventeenth until the middle of the eighteenth century the proportion of scientists born in Scotland who emigrated steadily increased: from then until about 1825 it tended to decrease, and in that year 71 per cent of the scientists selected for his sample died in Scotland, compared with 48 per cent in 1750. From 1825, however, the proportion of scientifically gifted Scots who emigrated has increased at an alarming rate, in spite of a slight evening off in the curve and even a recovery in recent years. Since a high proportion of the net loss of emigrants from Scotland of about 24,000 a year is from the more intelligent classes, Robertson urges that action is imperative if disaster is to be prevented. Scotland, he claims, produces 20 per cent of the British output of scientists and technologists, but only some 3 per cent of British scientific posts are available within her boundaries. Attributing the decline in the number of Scottish posts chiefly to the unequal distribution in Britain of research institutions, he urges that research institutes and posts in Scotland should be increased to about 10 per cent of the British total.

Museum of Applied Science of Victoria, Melbourne

The annual report for 1958–59 of the Museum of Applied Science of Victoria, Melbourne, records the welcome news that tenders have been accepted for building extensions and that it is hoped to complete the work by the end of 1960. As available space will be increased by about 50 per cent, this will be the greatest expansion of the Museum since its foundation in 1870 (Pp. 30. Melbourne: Museum of Applied Science of Victoria, 1960). Major displays include exhibitions celebrating one hundred years of State-operated railways in Victoria, present-day telephones, and a sectioned model of a reactor. The increasing interest in space exploration and upper atmosphere research led to the installation of a working exhibit showing satellites in orbit around the Earth. A working exhibit was also made to demonstrate the behaviour of a low-voltage halogen-quenched Geiger tube and its use for radiation measurement. The circuit includes a counting-rate meter for visual monitoring and a loud-speaker for aural monitoring.

Indexes for Scientific and Technical Reports

An investigation by the Research Department of the Association of Special Libraries and Information Bureaux into the indexing of published reports of scientific and technical conferences and symposia, prompted by an inquiry which cited some examples of unindexed publications of this type, established that half the published proceedings and reports of such conferences are provided with neither subject nor author indexes. Based on a survey of some 205 such publications noted in the British National Bibliography during January 1956–September 1959, inclusive, the survey showed that 59 per cent were without subject indexes and 66 per cent without author indexes, 50 per cent being without both. Publications of 301–400 pages were best provided with subject indexes (66 per cent), whereas 90 per cent of those of up to 100 pages were without, 71 per cent of those with 101–200 pages, 57 per cent of those with 201–300 pages, 54 per cent of those with 401–500 pages and 50 per cent of those with more than 500 pages. The position appears to be worsening, the percentage of publications without subject indexes in 1956 being 47; in 1957, 60; 1958, 61; and in

1959, 68, although the latter year is incomplete. A breakdown into broad subject groups showed that for biological and allied sciences the percentage without subject indexes was 53, and for physics, chemistry, engineering and technology, 60.

The report also notes the considerable time-lag between the holding of a meeting and publication of the report of its proceedings, and points out that publications which took more than two years to prepare were even less likely to contain subject indexes than those issued in the same year as the meeting. About a quarter of the reports were published by the organizers of the conferences themselves, and of these 79 per cent were without; about three-fifths of the remainder were issued by four publishing houses, and for these the percentages without subject indexes were 59, 96, 48 and 33. For the 22 reports issued by commercial publishers, the percentage without subject indexes was 35 per cent, and it is worth noting that all ten issued by one and seven out of eight issued by another had subject indexes. The risk that information sought in such reports may not be found is further illustrated by a more detailed example of a random sample of five publications, but this limited survey could not attempt to examine how far the contents of such reports are published elsewhere or caught up by abstracting organizations.

Leo III

An impressive addition to the field of the automatic office is *Leo* III, a new all-transistor digital computer under development by Leo Computers, Ltd. The machine, which incorporates many of the latest advances in data-processing techniques, makes use of a micro-programming construction and can perform arithmetical operations directly on decimal, sterling or any other desired quantities. The time taken for a typical decimal addition is 44 μsec. Perhaps the most interesting feature is that it is one of the first British computers to incorporate an automatic time-sharing facility. This enables two or more different programmes to be run on the computer at the same time and assists in obviating periods of waiting by (say) the arithmetic unit during the relatively slow operation of the peripheral equipment. Another feature is the large high-speed magnetic core store, which has a capacity of up to 32,768 words of 44 bits each. Further storage is provided by magnetic tape, each tape being capable of holding several million alpha-numeric characters, with a peak transfer speed of 90,000 characters per sec. A wide range of input and output devices is also available, and these include a line-printer with a maximum speed of 850 lines per min.

Radio Frequencies and Space Communications

The increasing demand for frequencies for various applications of radio technique has led to a state of congestion in the radio-frequency spectrum. At its autumn meetings in Geneva, the International Telecommunications Union gave earnest consideration not only to the more orthodox uses of radio-waves, but also to the requirements of radio astronomy and space research; and these must include in the near future the frequencies to be used for communications with and between vehicles in space. For the information of the United States Senate Committee on Aeronautical and Space Sciences, a report, by Edward Wenk, jun., has recently been issued under the title "Radio Frequency Control in Space Telecommunications" (United States. 86th Congress 2nd Session. Legislative Reference Service—Library of Congress. Pp. vii+235. Washington, D.C.: Government Printing Office, 1960). This report explains the dependence of the exploration of space on radio communication, reviews briefly the technical considerations which determine the selection of frequencies for various purposes, and summarizes the history of international agreements on frequency allocation. An outline is given of the organization of the International Telecommunications Union, with its technical advisory body, the International Radio Consultative Committee, and its relationship with the International Council of Scientific Unions, to which are affiliated the International Scientific Radio Union and the Committee on Space Research.

While most of the report is concerned with problems domestic to the United States in the allocation and control of radio frequencies for all purposes, some extensive appendixes include the report of the *ad hoc* Committee on the Peaceful Uses of Outer Space adopted by the United Nations General Assembly in 1959. There is also a world-wide summary of frequencies recorded by the International Frequency Registration Board of the International Telecommunications Union, and a copy of the Radio Regulations and Frequency Allocations adopted by the Administrative Radio Conference of the Union at Geneva in 1959. These appendixes make the U.S. report a very useful work of reference to those interested in international radio matters.

Tectonics of the Gobi Mountains

The aerial and land survey of the fault and fissure zone in the Gobi mountain range, as resulting from the earthquakes of December 7, 1957, and April 7, 1958, is discussed by V. P. Solonenko and N. A. Florensov (*Priroda*, 2, 61; 1960). The disturbed zone stretches almost parallel to latitude 45° N., and extends for almost 300 km. from longitude 99° E. to 102° 20′ E. The zone consists of a number of faults, one with a visible throw of 328 m., enclosing several horsts and rift-valleys, one rift-valley having dimensions 27 km. long and 800 m. wide.

Newly Discovered Rock Shelter Art in Malaya

Why mankind should want to draw and paint in caves and rock-shelters cannot as yet be determined. Probably the reasons are multiple. In the case of palæolithic man, it is likely that sympathetic magic in connexion with food supply was the motive, but such an urge cannot be adduced in the case of the South and Central African rock-shelter art, nor in the case of some newly discovered decorated rock-shelter walls near Ipoh, Perak, Federation of Malaya. These latest discoveries were made by Lieut. R. L. Rawlings, of the Gurka Rifles, and are described in *Man* for January 1960 by J. M. Matthews, curator of museums, Federation of Malaya. Animals, men and designs are depicted in various shades of hæmatite (red), and at least three styles can be distinguished. Most of the caves in Malaya have been dug for cave earth and guano, so there are few undisturbed deposits. No correlation of this new-found art with any known culture is possible. Comparison of drawings made in one area with others elsewhere on stylistic grounds is more than dangerous; most of these drawings are essentially simple, and any conventionalizations are what one might expect to occur anywhere independently. Some day the age of this Malayan art will become known, and also why it was made. In the meanwhile, one must be grateful for the excellent account here given.

The First Forty Years of the Royal Society of London

An exhibition has been arranged at the Science Museum to illustrate the first forty years of the Royal Society of London. The exhibition is mainly biographical, and illustrates the scientific life and work of some twenty men, who were distinguished Fellows during the period 1660–1700. The exhibits consist of a collection of portraits (enlarged photographs of engravings), copies of the Fellows' scientific publications, photographs of early documents of the Society, and a small collection of instruments and apparatus.

British Men of Science

To coincide with the tercentenary of the Royal Society, the preparation of a new series, *British Men of Science*, is announced by Nelson under the general editorship of Sir Gavin de Beer. The series will be designed to provide authoritative but short lives, written by leading scientists and intended for the general reader and university student. So far, twelve volumes are in preparation, but others are being actively planned. They are: "Joseph Black", by Prof. Douglas McKie; "Charles Darwin", by Sir Gavin de Beer; "Humphry Davy", by Sir Harold Hartley; "Edmond Halley", by Sir Harold Spencer Jones; "William Gilbert", by N. H. de V. Heathcote; "William Herschel", by Angus Armitage; "Charles Lyell", by Sir Edward Bailey; "William Henry Perkin", by Prof. John Read; "Joseph Priestley", by F. W. Gibbs; "Ernest Rutherford", by Sir Ernest Marsden; "Michael Scot", by Prof. Lynn Thorndike; "Joseph John Thomson", by Sir George Thomson. The series, which will be fully illustrated, is to be in line and half-tone and will contain a list of books for future reading.

"Non-Enzymic Reactions of Indoles with Coenzyme I"

Prof. S. G. A. Alivisatos, G. A. Mourkides and A. Jibril write: "In a previous communication (*Nature*, 186, 718; 1960) we described certain interactions occurring between indoles and coenzyme I. While recent evidence obtained in our laboratory with a number of other indoles and with the reduced form of coenzyme I confirmed our original observations, pointing towards an interaction of the indole with the nicotinamide moiety of the oxidized form of coenzyme I (probably, a charge transfer complex), the previously reported decrease in absorbancy observed in the ultra-violet region below 310 mμ was later shown to be an artefact produced by stray light when one of the reactants was present at high concentration in the blank".

Announcements

Prof. P. B. Medawar, C.B.E., F.R.S., Jodrell professor of zoology and comparative anatomy at University College in the University of London, has been appointed director of the National Institute for Medical Research, Mill Hill, London, as from August, 1962. Prof. Medawar succeeds Sir Charles Harington.

The following have been elected honorary members of the American Institute of Nutrition: Lord Boyd Orr, Drs. W. A. Aykroyd, F. B. Berry, F. R. Boudreau, R. C. Burgess, F. W. Clements, Dr. D. P. Cuthbertson, V. N. Patwardhan, Prof. E. F. Terroine and Prof. A. I. Virtanen. This is the first occasion on which the Society has elected honorary members.

Dr. J. H. Gerber has been appointed director of the Center for Aging Research of the National Institutes of Health, U.S. Department of Health, Education and Welfare, in succession to Dr. G. Halsey Hunt, who is now chief of the Division of General Medical Sciences, of which the Center is a component.

Dr. J. J. Gilman, of the Research Laboratory, General Electric Co., Schenectady, is to give a lecture on "The Physical Nature of Plastic Flow", under the auspices of the Metal Physics Committee of the Institute of Metals. The meeting will be held at the Institute's headquarters, 17 Belgrave Square, London, S.W.1, on Tuesday, August 16, and from which further information can be obtained.

The Belgian Society of Pharmaceutical Sciences is organizing an International Symposium on Chromatography in Brussels during September 16–17. Further information can be obtained from the Belgisch Genootschap voor Pharmaceutisches Wetenschappen, 11 Archimedesstraat, Brussels 4.

The Universities Federation for Animal Welfare is holding a Summer Congress at Culham College, Abingdon, Berks, during September 16–22. Further information can be obtained from UFAW (Summer Congress), 7*a* Lamb's Conduit Passage, London, W.C.1.

A non-residential summer school on "Numerical Analysis" will be held in Oxford during September 26–October 7. The object of the course is to teach the elements of numerical analysis in the fields of linear algebra and differential equations to users of automatic digital computers in industry, government and university departments. Further information can be obtained from the Secretary to the Delegacy for Extra-Mural Studies, Rewley House, Wellington Square, Oxford.

The fifth International Instruments and Measurements Conference and Exhibition are to be held in Stockholm during September 10–17. The Conference is organized by the Royal Swedish Academy of Engineering Sciences and the Swedish Association of Technical Physicists. Further information concerning the British participation can be obtained from the Chief Press Officer, U.K. Atomic Energy Authority, 11 Charles II Street, London, S.W.1.

The first British Congress on "The History of Medicine and Pharmacy" is to be organized by the Faculty of the History of Medicine and Pharmacy at the Worshipful Society of Apothecaries of London, in co-operation with the Royal Colleges and the Royal Society of Medicine, and held in London during September 29–30. Further information can be obtained from Dr. F. N. L. Poynter, Wellcome Historical Medical Library, The Wellcome Building, Euston Road, London, N.W.1.

As from July 31, the Imperial College of Tropical Agriculture is to be merged into the University College of the West Indies, and the College will be known as the University College of the West Indies, Faculty of Agriculture (Imperial College of Tropical Agriculture), Trinidad, West Indies. The London office of the College is to be closed as from August 31.

DOCTOR RUGGLES GATES AND THE ABORIGINAL AUSTRALIAN

By Prof. A. A. ABBIE
Department of Anatomy, University of Adelaide

DR. R. RUGGLES GATES has recently published two papers on the Australian aborigines. One deals with some genetical aspects of 'race' crossing[1], the other with the homogeneity or otherwise of the aborigines[2]. The first reaction to these papers is of profound admiration that so much could result from so brief a visit and that such far-reaching conclusions could be extracted from such scanty material.

I am not a geneticist but over many years have had close personal contact with large numbers of aborigines in most parts of the continent and it is against that background that Dr. Gates's contributions are considered here.

In the first place it is necessary to point out that Dr. Gates is correct in many of the statements he makes—this is when he is repeating the findings of earlier workers. His paper on the genetics of interbreeding[1] is beyond my competence except to express surprise at the confidence with which Dr. Gates supplies pedigrees when, in truth, aboriginal marriage customs and beliefs render the compilation of a genealogical tree almost entirely a matter of faith (in this connexion, see Abbie and Adey[3]). His second paper is concerned mainly with full aborigines and raises a number of points (some are common to both papers) that deserve further consideration. The most important relate to pigmentation, hair-form, stature and head-form and they will be reviewed in that order.

Aborigines are born pinkish yellow (not white) and darken in a few weeks or so according to the degree of solar exposure. We have never seen a sacral ('mongolian') spot. Darkening of the skin usually stops at a warm medium vandyke, but it may darken further on intense exposure in the desert or in the extreme north. Protection from the Sun, as in fat creases, but more particularly when clothing is worn habitually, causes the skin colour to fade—sometimes almost to the original pinkish yellow—and in the latter case undue exposure may lead to quite severe sunburn[3,4]. Dr. Gates is evidently aware of this work yet he attributes a yellowish shade in some northern Queensland natives to 'Tasmanian' affinities, a fair example of ignoring facts to push a hypothesis. In central Australia particularly, but also in South Australia, many of the children are fair-headed, the colour ranging from completely flaxen to almost rufous brown and darkening with age[3-5]. Dr. Gates appears to support Birdsell's[6] view that this condition appeared first in the south-west of central Australia and is spreading more or less concentrically outwards and especially westwards. In fact, the condition was first described in Western Australia (at New Norcia) in the middle of the last century, and Griffith Taylor's original observations on fairheadedness were also made in Western Australia. We have noted fairheadedness on the south coast at Fowler's Bay; in central Australia it is widespread but with a patchy distribution that does not support the conception of continuous centrifugal spread. But we have also found fairheadedness (though less frequently) in the extreme north of Arnhem Land where the possibility of spread from central Australia is practically zero. In any event, since intertribal breeding was, and still is, virtually unknown except recently on Government Settlements, what mechanism can be adduced to account for the spreading ?

Dr. Gates puts great reliance upon the occurrence of curly or frizzy hair (associated with short stature) to establish the 'negrito' character of some northern Queensland aborigines. Photographs of these people published by Tindale and Birdsell[7] reveal hair-forms from practically straight to deeply curled, and that is what is found normally in all aboriginal groups anywhere in the continent[4,5]. In the extreme north curly-to-woolly hair is commoner than elsewhere but there is some evidence of Indonesian and Melanesian admixture (including blood group B). Also, Dr. Gates does not take into account (although he is aware of the fact) that in the last century some thousands of male 'kanakas' of Melanesian origin were imported into northern Queensland to harvest sugar cane. They were afterwards repatriated but scarcely, one imagines, without leaving their mark on the local aboriginal population. The most tightly curled hair seen by me belonged to a Pitjantjara male in central Australia, about as far away from the coast in any direction as it is possible to get.

Stature Dr. Gates considers diagnostic of the 'negritos' of northern Queensland. For 9 Monamona males he gives a range of 141·5 cm.–161·5 cm., with a mean of 155·8 cm. However, the shortest is an acknowledged dwarf: without him the range is 150·0 cm.–161·5 cm., with a mean of 157·6 cm. Our (unpublished) figures, based upon about 30 adult males in each case, for four areas across the continent are: south (Fowler's Bay): 146·0 cm.–174·0 cm. (mean 163·1 cm.); centre (Pintubi): 152·0 cm.–180·7 cm. (mean 167·1 cm.); (Wailbrai): 159·5 cm.–180·1 cm. (mean 170·3 cm.); northern Arnhem Land (Burera): 150·4–187·3 cm. (mean 169·6 cm.). Clearly there is an enormous overlap and it seems at least possible that had Dr. Gates examined a larger sample he would have been less positive about the pygmoid character of the northern Queensland aborigines. The shortest adult male aborigine so far recorded[8] measured only 135 cm.; he was found in the Peterman Range near central Australia, but short people occur anywhere. Dr. Gates believes that half-castes show heterosis, being larger, better formed and more fully developed; this we cannot confirm.

The shape of the skull is another factor Dr. Gates adduces to support his views on the 'negrito' character of north Queensland aborigines. The range of cephalic indices in his series of 9 was 70·56–81·76, with a mean of 74·48 (the highest index came from the dwarf previously mentioned). Corresponding figures for our groups were: Fowler's Bay: 68·2–79·2 (mean 73·3); Pintubi: 66·2–81·4 (mean 71·5);

Wailbrai: 67·4–84·3 (mean 73·5); Burera: 64·2–80·0 (mean 70·9). Obviously, while the ranges are wider, some of these means are very close to the northern Queensland mean, and many of these heads are much more brachycephalic. Indeed, if the dwarf were eliminated the Monamona mean would not differ materially from any other aboriginal mean. One further point: while Dr. Gates tacitly endorses my view[9] that head-length and head-breadth vary independently, he evidently did not read far enough to gain some insight on brachycephaly. It is true that, *ceteris paribus*, head-length is determined genetically (subject to some environmental modification as Boas has shown) in fully developed adults, but it is not necessary to invoke any involved genetic mechanism to explain short-headedness in pygmoid people. These are in an infantile state of development and their heads betray the characteristically infantile brachycephaly.

There is no space here to mention a number of factual errors in Dr. Gates's papers, and certainly no necessity to follow his excursions into archæology and geology. Perhaps it is best to conclude with one's own views, based upon the examination of several hundreds of aborigines in various, widely separated, parts of the continent.

Aborigines betray a fairly wide range of physical variation, but such variation is intratribal, not intertribal. That is, the tribes, practically anywhere, show a parallelism in the range of variation, and the means for the tribes come out remarkably close to each other. This implies a high level of physical homogeneity throughout the continent—all the more singular because the maximum aboriginal population is said never to have exceeded some 300,000 and such a small number, dispersed in small inbreeding groups throughout an area of nearly 3,000,000 square miles, surely had little chance of achieving such uniformity by interbreeding. On the contrary, genetic drift in what were practically isolates would be expected to produce a wide physical diversity from one end of the continent to the other. The fact that what diversity occurs is but slight points to a few tentative conclusions. It suggests first that the initial aboriginal landing comprised only a relatively small party bringing only a limited genetic pool. The second conclusion is that there had been a minimum of subsequent admixture with other peoples before the advent of Europeans. Thirdly, the aborigines could have occupied Australia for only a relatively short period—certainly not long enough to produce any obvious physical differences from place to place. This last is in harmony with their uniformly mesolithic culture[5] and with carbon-14 datings which, so far at least, cannot certainly be associated with human occupation beyond about 6,000 B.C.

HERBICIDES AND THE SOIL

MODERN techniques of herbicidal applications fall into two groups. Direct application may be made to the soil followed by absorption through the roots or applications may be made to the foliage where entry is largely dependent on penetration through the leaves. This distinction is not, however, clear cut, since with foliar applications some of the droplets will fall on the ground while some of the compound may be washed off the leaves by rain. Thus for both types of technique it is of major importance to ascertain how long individual compounds persist in the soil, what are the physical or biological factors which cause their removal or decomposition and what are the effects on the fauna and flora of the soil. It was against this background that the British Weed Control Council organized a symposium on "Herbicides and the Soil", which was held in the Clarendon Laboratory, University of Oxford, on April 7.

The opening speaker was Prof. L. J. Audus (Bedford College, London) on "Microbiological Breakdown of Herbicides in Soils". Before direct investigations on the rate of decomposition of herbicides was undertaken it had been observed in the field that the persistence of some, as judged by the effects on plant growth, was minimal when the soil was moist and warm, conditions generally accepted as being favourable to micro-organisms. Since these conditions could also favour chemical decomposition it was difficult to separate the operative factors except in the laboratory. The fact that breakdown in the soil was largely arrested by autoclaving and that the addition of compounds known to be inhibitory to micro-organisms also slowed down the rate of decomposition pointed to the conclusion that micro-organisms were involved.

If micro-organisms are responsible for the breakdown of a herbicide, then the addition of such a compound to the soil under constant and favourable conditions will not result in immediate breakdown, as in a chemical process, but there will be a lag phase while there is a build-up of the population of the effective organisms.

At Bedford College the perfusion technique has been employed to study the breakdown of substituted phenoxyacetic acids and in every case the existence of a lag phase has been demonstrated. It has also been established that once decomposition has taken place in a soil, then the speed of breakdown of a further addition of the chemical is increased.

In 1950, Audus isolated an organism of the *Bacterium globiforme* group which was able to multiply on an agar medium containing 2,4-dichlorophenoxyacetic acid as the sole source of carbon. This organism, when added to garden soil, immediately accelerated the rate of breakdown of 2,4-dichlorophenoxyacetic acid. Since this original isolation, it has been found that a wide range of bacteria, actinomycetes and fungi are capable of using herbicides as their only source of carbon.

For the substituted phenoxyacetic acids there is no clear correlation between the duration of the lag phase and chemical structure, but it is apparent that the position on the ring of a single chlorine substituent is important; for example, a change of the substituent from the 4 to the 2 position makes the compound much more resistant to attack. In di- and tri-substituted compounds the presence of a 4-chloro substitution overrides the influence of other substitutions. N. Brownbridge, however, sought to discover whether ease of breakdown was linked with the level of phytotoxicity of the chemical to higher plants as judged by the concentration necessary to reduce the rate of growth of cress roots by 50 per cent. Excluding the value for 2-chloro-4 methylphenoxyacetic acid, there was a highly significant inverse correlation. The position of 2-chloro-4 methylphenoxyacetic acid was anomalous; the lag phase was far too long, judged on the degree of phytotoxicity.

If a soil was first treated with 2-chloro-4 methyl phenoxyacetic acid and another substituted phenoxyacetic acid was then added, the breakdown of the second compound was rapid; for example, even after prolonged perfusion 2,4,5-trichlorophenoxyacetic acid is very slowly decomposed but 2-chloro-4 methylphenoxyacetic acid treated soil can break down 2,4,5-trichlorophenoxyacetic acid more readily. Soils first treated with other phenoxyacetic acids did not gain the power to attack other compounds to the same extent.

Prof. W. W. Fletcher (West of Scotland Agricultural College, Glasgow) spoke on the "Effects of Herbicides on Soil Micro-organisms" and emphasized that although a few chemicals did reduce the population of the soil micro-organisms, the net effect was ultimately one of stimulation as one or more species became adapted to use the herbicide as a substrate. Organisms responsible for nitrification and nodulation appear to be more sensitive than other bacteria to a wide range of herbicides including sodium chlorate, 2-chloro-N,N-diethylacetamide and 2-chloro-N,N-diallylacetamide when applied at normal rates in the field. There is a general agreement that 2-chloro-4 methylphenoxyacetic acid, 2,4-dichlorophenoxyacetic acid and 2,4,5-trichlorophenoxyacetic acid at the normal rates employed in agriculture have no adverse effects on the total number of micro-organisms, and it would appear that 2,2-dichloropropionic acid augments rather than depresses the general soil population.

The species of one genus may vary greatly in their response to chemicals. For example, 3,5-dinitro-*o*-cresol inhibited *Rhizobium lupini* at 198 p.p.m., whereas *R. meliloti* and *R. leguminosarum* required 1,980 p.p.m. for inhibition.

Dr. G. S. Hartley (Chesterford Park Research Station) spoke on the "Physico-chemical Aspects of the Availability of Herbicides in Soils". Beginning with a simple theoretical model, Dr. Hartley defined his problem within the system—soil particulate structure–air–water–herbicide.

In the simplest case, if the water content is at 'field capacity' and a non-volatile water-soluble herbicide is applied uniformly to the soil surface, then as long as the system remains undisturbed the herbicide can move only by diffusion in the water phase. The rate of this movement can be calculated and for molecules of the size of herbicides 1 per cent of the applied chemical will move rather more than 2 ft. downward in three years. The presence of solid matter in such a system as well as air locks reduces the 'expected' rate of diffusion. When corrections for these obstacles are applied to the theoretical figure it is apparent that 1 per cent of an applied soluble herbicide might take twelve years to reach a depth of 2 ft. It must therefore be concluded that the downward movement of herbicides in the field is not by diffusion alone.

Again in an ideal uniform system, and assuming field capacity to be 25 per cent v/v, 10 cm. of rainfall would sweep a readily soluble herbicide to a depth of 40 cm., where it would be localized in a narrow band. In the field where a soil is heterogeneous the herbicide will move unevenly downwards. This unevenness is especially marked if rainfall is heavy, when the herbicide is washed down the larger channels or cracks in the soil. Dr. Hartley suggested that the difference between observed and calculated rates of movement could be largely explained in terms of the heterogeneity of the soil system.

Attempts to measure the rates of movement of herbicides downwards have all departed from field conditions by applying 'rainfall' at extremely heavy rates and thereby introduced large errors. Relatively insoluble herbicides go into solution slowly; for example, a sphere of trichloroacetic acid 5μ in radius might dissolve in seconds, whereas a sphere of simazine of identical size would take 30 hr. Therefore, unless rainfall is prolonged, the more insoluble substances may resist leaching due to their failure to go into solution, although sufficient water *in toto* may be applied to take all herbicides into solution.

Upward movement of a herbicide in the soil is induced by the evaporation of the soil water. Evaporation will take place almost entirely from the surface of a wet soil, but as the capillary conduction system breaks down the rate of loss of water falls sharply. This upward movement of herbicides will accentuate a tendency for herbicides to be concentrated near the surface of the soil in dry weather.

Even at a rate of application of 100 gal./acre the sorption of a spray solution into the capillaries of a dry soil lump can be quite pronounced and subsequent release of the chemical from such places is by the slow process of diffusion. The only way to counter this appears to be spray when the soil is wet. The development of granular herbicides promises to overcome some of these difficulties since the amount of rainfall necessary to extract the herbicide from the granule is probably sufficient to ensure thorough wetting of the easily accessible sites in the soil before the granules release their active content. A simple experiment using a freely soluble dye added to plaster-of-paris columns showed that the extraction of the dye passing through the columns was far more complete and far quicker if the columns were first wetted with water.

Dr. W. van der Zweep (Wageningen) contributed to the meeting a consideration of the practical use of herbicides in relation to their persistence in the soil. Frequently, the rate of application and the chemical used are determined by the persistence that can be tolerated by the following crops. In certain cases control and not eradication of weeds is a penalty that must be accepted if a following crop is to be safeguarded. Mechanical incorporation of a chemical into the soil increases the persistence if the chemical has a high vapour pressure. In other cases incorporation improves the effectiveness of the chemical and also assists subsequent breakdown so that a following crop may be sown with increased safety. Persistence may be varied according to the formulation of the chemical used. Dr. van der Zweep brought his contribution to an end by appealing for information on the half-life of herbicides, a half-life determined in the first instance in standardized laboratory tests. Such a system could be extended to field studies where the variation would be apparent and could be measured.

The full proceedings of the meeting together with reports of the discussion which followed each paper will be published by Blackwell Scientific Publications, Ltd., later this year.

COLLOID AND POLYMER SCIENCE

CONTINUING earlier seminars[1] in the Department of Chemistry of University College, London, nine lectures were given during February 25–March 18. Drs. C. H. Bamford and J. A. Kitchener summarized work (some of which has been published[2,3]) on calculation of free-radical reactivity and stability of colloidal model suspensions. Prof. J. A. V. Butler discussed some flow properties of dilute solutions of deoxyribonucleic acid in 0·2 *N* sodium chloride, the rate of shear being varied in the range 0·5–30,000 sec.$^{-1}$. At the high rate of shear no permanent change of the solute occurred, but some disentangling of networks. Using the theories of Kuhn and Kuhn[4] and Cerf[5], for the results obtained at low rate of shear, it appears that the deoxyribonucleic acid molecule is somewhat flexible. Dr. P. W. Allen described the grafting of methylmethacrylate polymers on natural rubber latex using hydrogen peroxide, together with a polyethylene amine, as initiators. Under these conditions the graft co-polymer is mainly formed on the surface of the latex. If oil-soluble initiators are used, polymerization of methylmethacrylate occurs inside the latex. Dr. C. Robinson reviewed recent work[6] on liquid crystals of synthetic polypeptide and described a new effect: if a concentrated solution of poly-γ-ethyl-L-glutamate is illuminated with white light, brilliant iridescent colours are reflected. This is explained as an optical analogue of an X-ray powder diagram. There are indications that deoxyribonucleic acid solutions can also form liquid-crystals.

Prof. A. Katchalsky discussed the application of the thermodynamics of irreversible processes[7] to the study of colloid–chemical phenomena. The treatment of entropy production as the sum of the products of generalized forces and conjugated flows was outlined. Sufficiently slow flows are linearly dependent on all the forces operative in the system, through a set of phenomenological equations, the coefficients of which obey Onsager's law[8] and constitute a symmetrical matrix. The phenomenological equations provide a convenient formal framework for the description of electrokinetic phenomena[9], and permit the establishment of the classical Saxen relations on a thermodynamic basis. A similar treatment[10] of polyelectrolyte solutions leads to new correlations between transport phenomena, such as diffusion, sedimentation and conductance. The thermodynamic approach is useful in the analysis of membrane permeability[11–13]: contradictions inherent in the conventional equations do not occur and a consistent set of equations is obtained, suitable for the description of the transport of electrolytes and non-electrolytes through membranes[14]. The coefficients of these equations were transcribed in terms of frictional forces and distribution coefficients, which characterize the interaction of the permeant solutes with the membrane. In the last lecture, Prof. Katchalsky discussed some fundamentals of mechanochemistry[15].

EFFECTIVENESS IN INDUSTRY

THE presidential address of Mr. W. E. Bargett to the Institution of Metallurgists, though specifically directed to that profession, had much of direct interest for other technologies. In discussing the training of both graduates and juniors he pointed out the necessity of realizing that the former, though 'educated', have still to receive a 'training' even if during this period they can give little immediate return for their salaries. Equally, "the inefficient utilization of junior people's time is out of keeping with the demands of industry for greater numbers of well-qualified technologists and must be eliminated through sheer economic necessity". It is a general experience that a bright junior is quickly frustrated when called upon to do repetitive work which provides little experience and makes no particular intellectual demand. The interesting suggestion was made that a solution of this problem might be found by employing older people who may have had no special training, but who have sufficient intelligence to learn all that is required to carry out specific operations, appreciating not only what to do but also why it is done in a certain way. Experience has shown that there is no difficulty in filling posts of this kind very successfully. They have, indeed, a certain attraction for a particular type of man who is satisfied to continue doing a routine job.

Mr. Bargett, though appreciating the temptation to look for rapid solutions of industrial problems, expressed his strong belief that the effort expended would be more efficiently used in gaining a fuller understanding of the problem itself, that is to say, in finding the best, rather than the quickest, solution. Concluding with a few examples drawn from his own work to illustrate the points made, he mentioned the search for an answer to the urgent problem of overcoming the service-cracking at elevated temperatures of a low carbon steel containing $\frac{1}{4}$ per cent molybdenum. The suggestion that the trouble was due to grain-boundary effects which might be eliminated by the addition of 0·002 per cent of boron proved successful, but also, as a most unexpected by-product, led to the yield-point of the steel being doubled and the tensile strength being raised by 50 per cent. Further work led to the production of a weldable steel with a tensile strength of 70 tons per sq. in. in the air-cooled condition.

HEALTH SERVICES IN THE U.S.S.R.

IN October 1958, twenty-three individuals from twenty-one countries and territories were invited by the World Health Organization to visit the U.S.S.R. to study its health services. Some of the members of the group were public health administrators, others were medical specialists, and all were engaged in medical or health work in their own countries. An extensive itinerary was planned by the Government of the U.S.S.R. in order to allow the group to see as much as possible of the country's health services during their stay of a little over five weeks. On their return, the members of the group prepared a report which has recently been published*.

The health services in the U.S.S.R. are organized to meet the requirements of a specific social system and philosophy, and are designed to provide comprehensive medical care for the whole population through the integration of curative and preventive services at all levels of administration. The basic health philosophy in the U.S.S.R. is one of 'prophylaxis' by health protection, and it places the responsibility for the health of the people on the State. The Soviet Government has recognized the part played by health in the economy and development of the country, and the fact that certain population groups (children, workers, etc.) require specialized medical attention.

The existing health services of the U.S.S.R. are the result of development during a period of forty-years research. The complicated structure evolved in this way consists of a number of institutions and functional units so interlocked that the result is a unified system embracing all health disciplines and reaching into every locality in the fifteen constituent republics, to the smallest and most remote villages and farming areas. The basic principle of this structure is highly centralized planning and supervision, coupled with almost complete executive and operational decentralization, permitting about 90 per cent of problems to be dealt with at local levels, without disturbing the general and basic pattern in any way.

The various units constituting the organizational structure of the health services of the U.S.S.R. may be classified into six groups, each group representing a defined function. The six functional groups are: (1) the directing, planning and supervising group; (2) the academic and scientific group; (3) the advisory group; (4) the educational group; (5) the executive group; (6) the operational group.

The health services of the U.S.S.R., both preventive and curative, are available to the whole population free of charge, regardless of social and economic status. The services of health workers, whether highly trained medical specialists or trained *feldschers*, reach every home even in the most remote and isolated localities. This is possible because of the 'State' character of Soviet medicine, and although private practice is not forbidden, it is so restricted that it exercises no influence whatever on the general set-up of health services in the country. The State character of Soviet medicine is further illustrated by the structure of the health budget for the Union. The health budget for 1958 makes provision for an expenditure of more than 40 billion roubles. This means that approximately 200 roubles will be spent for every member of the population in one year. But this does not represent the total expenditure for health in the Union, for apart from the official budgets, other bodies and institutions are also required to budget for additional expenditure on health.

The collective farms provide the buildings and equipment, and bear most of the cost of maintenance of their own health units and maternity homes; the health authorities are only responsible for the salaries of medical and para-medical staff. The same applies to industrial concerns. Furthermore, only part of the capital cost of buildings comes from the official health budget. Finally, certain medicines prescribed for ambulatory patients have to be paid for by the patients themselves.

The Soviet concept of health has resulted in a realignment of services which appears to be unique. There are three main medical fields in the U.S.S.R.: (*a*) adult medicine, (*b*) child medicine, (*c*) hygiene and sanitation.

Soviet scientists feel quite strongly that a child is not just a miniature adult: it is a different being with its own specific physical and physiological functions, and therefore requires a specific medical approach. Paediatrics is therefore not a post-graduate speciality of general medicine, but rather a separate study which begins during the undergraduate period. A medical student must choose at the beginning of the third year of his course whether he wants to become a doctor for adults, or a doctor for children, and, depending on the choice, will follow a different line of study.

The third medical field is that of hygiene, which produces graduates known as 'hygienists'. Preventive medicine is divided into (*a*) personal preventive services, which are integrated into the respective fields of adult and childhood medical studies, and (*b*) non-personal services (including environmental and occupational health), which constitute the major subjects at the undergraduate faculties of hygiene. Hygienists staff the sanitary and epidemiology stations and may further specialize in nutrition, municipal hygiene, and industrial hygiene. It appears that, in many respects, the medical hygienists of the U.S.S.R. fill the posts usually occupied by sanitary engineers in other countries.

* World Health Organization. Public Health Papers, No. 3: Health Services in the U.S.S.R.: Report prepared by the Participants in a Study Tour organized by the World Health Organization. Pp. 58. (Geneva: World Health Organization; London: H.M. Stationery Office, 1960.) 2 Swiss francs; 3s. 6d.; 0.60 dollar.

Scientific research is a most important function of all medical units in the U.S.S.R. Research is planned and co-ordinated, however, and it includes basic, clinical, applied and operational aspects. The system of special research institutes and advisory councils, together with the hierarchical structure of research units, ensures the proper utilization of funds and directs research towards the more pressing problems of the nation.

All heads of divisions and departments of the medical services are medical graduates. Even those departments which deal with sanitary engineering, nursing and para-medical training are headed by doctors. There is no nursing council as such, and the post of sanitary engineer is non-existent. Engineers are attached to departments dealing with buildings and construction, but their task is that of a constructional engineer rather than of a specialized sanitary engineer. The lay sanitarian or sanitary inspector, as known in other countries, is unknown in the U.S.S.R., and his task is performed by doctors, assisted by *feldschers*. Nor are the posts of social workers and social anthropologists known in the U.S.S.R.

The number of doctors in the U.S.S.R. is high, there being about one doctor to every 570 of the population, and in some regions, such as Georgia, as many as 1 in 400. The ratio of male to female doctors is about 50 : 50, but in some areas 70 per cent of practising doctors are women. The total number of medical graduates in the U.S.S.R. in 1957 was 360,000, a striking increase over the figure for 1913, which was 23,000. It is estimated on the basis of existing facilities for medical education that, by the end of the new 'seven-year' plan in 1965, there will be 490,000 doctors in the country, which will give a ratio of one doctor to every 460 inhabitants.

There were also 99,921 mid-wives working in the U.S.S.R. in 1957, as well as 71,151 *feldscher*-mid-wives and 14,714 *feldschers*. It is estimated that by 1965 there will be 1,470,000 qualified nurses in the country, or 3 qualified nurses to every doctor.

BIOLOGICAL EFFECTS OF ATOMIC RADIATION

IN 1956, a report with this title was published by the U.S. National Academy of Sciences. It contained the findings and recommendations of six committees dealing with genetics, pathology, meteorology, oceanography and fisheries, agriculture and food supplies, and disposal and dispersal of radioactive wastes. During the intervening years these committees have continued to collect information in their separate fields, and they have now published their findings and conclusions in the same form as before[*]. The report is shorter than the first one, in which much space had to be devoted to explanations of fundamental scientific facts and principles. The presentation is again admirably clear and as free from technicalities as possible; the main points are condensed into a separate, concise and easily understood "Report to the Public". Several appendixes bring more detailed information and calculations; technical reports are in preparation. The following are some of the more important statements.

At present, delayed fall-out from the stratospheric reservoir is the major source of airborne artificial radioactivity and will remain so unless large-scale testing is resumed. There is a non-uniform distribution of strontium-90 in fall-out, with a maximum at lat. 40–50° N. Fall-out is greatest in spring and is mostly brought down by precipitation. The half-residence time of radioactive debris in the troposphere is about 2–4 weeks; in the stratosphere it depends on the latitude at which the debris was injected. For injections in equatorial regions, the half-residence time is 2–5 years; for injections in temperate and polar zones it is less than 1 year. If there are no further additions to the atmospheric burden, most of the remaining radioactivity in the atmosphere will have settled down by 1962–63; the ground concentration will then be about twice that of November 1958. It is certain that all living things, man included, now have a radioactive body burden higher than in the pre-atomic era, and although the present levels in foodstuffs are low, the cumulative and retained isotope burden in man must be considered.

The estimate of genetical radiation damage has gone up as a result of the recent increase in fall-out and the previously unconsidered contribution to it of carbon-14. On the other hand, the finding that in spermatogonia and oocytes—but not in mature spermatozoa—of mice and *Drosophila* a given dose of radiation produces fewer mutations when administered at low than at high intensity may mean that previous estimates of genetical radiation damage have erred on the high side. In the absence of more information on the effects of dose-rate and dose-fractionation, the committee continues to recommend that for the general population the average gonadal dose accumulated during the first 30 years of life should not exceed 10 r. of man-made radiation, and should be kept as far below this as practicable. In human tissue cultures, doses of 25 r. produce detectable chromosome breakage in a significant proportion of cells. A slight, but statistically significant, deviation from the normal sex-ratio was observed among children of survivors of the Japanese atom bomb explosion; possibly this might be due to the action of sex-linked mutations affecting prenatal viability.

In animals, a shortening of life-span through radiation has been observed not only for the irradiated individuals themselves, but also for their progeny. In man, shortening of life has not been demonstrated after small doses, but is expected to occur after substantial doses of whole-body irradiation. Part of

A Report to the Public on the Biological Effects of Atomic Radiation based on the 1960 Summary Reports of the National Academy of Sciences Committee on the Biological Effects of Atomic Radiation. Pp. iii+19. (Washington, D.C.: National Academy of Sciences–National Research Council, 1960.)

this expected decrease in life-span will be due to leukæmia, which is known to affect over-exposed individuals with more than average frequency. The question whether diagnostic X-radiation during pregnancy increases the incidence of leukæmia in the children cannot be decided on the available evidence. Neither can it be decided whether there is a lower threshold to the production of tumours and leukæmia by irradiation, but the sub-committee dealing with hæmatological effects thinks it prudent to assume that for leukæmia no threshold exists. Mammalian embryos are readily affected by low doses of ionizing radiation. One of the most sensitive known indicators of chronic biological damage is the gradual reduction in number, motility and viability of sperm, resulting from small chronic radiation over-exposure. In dogs, effects on sperm have been observed at chronic dose-rates of only ten times the maximum permissible value for human occupational exposure.

Considerable space is devoted to recommendations for future research, especially in the field of genetics. The need for basic research is stressed, and the relevance of mutation research on all forms of life, including bacteria and viruses, is pointed out. On the other hand, attention is directed to problems that arise in human populations and have no counterpart in animal societies. Thus: "human society depends upon a diversity of performance among its members and on very high mental qualities among a few of them. A human civilization might collapse by becoming qualitatively inadequate, even though reproductive selection of certain kinds were acting at high intensity and the number of individuals in the population remained at a level that was previously optimal". These sentences have an obvious relevance to the questions discussed in the leading article "Evolution of Mankind" in *Nature* of February 13.

MODERNIZATION OF THE STOCKHOLM CYCLOTRON

In two papers published during 1952, H. Atterling and G. Lindström described the initial performance of the fixed frequency 225-cm. cyclotron at the Nobel Institute of Physics, Stockholm (*Arkiv för Fysik*, 4, 559; 1952, and *Nature*, 169, 432; 1952). A more detailed description of the machine, which has operated reliably and stably for several years producing internal beams of protons, deuterons, alpha-particles and heavy ions (carbon, nitrogen, oxygen and neon ions), is given in two recent articles in *Arkiv for Fysik* (15, 483 and 531; 1959). The oscillator-frequency used recently is 8·1 Mc./s. and with this frequency the machine accelerates ions to a nominal energy of about 11 MeV. per nucleon at a radius of 90 cm. Internal beam currents of approximately 300 μamp. of 22-MeV. deuterons are obtained.

In March 1958, the cyclotron was shut down and taken to pieces for remodelling. Previously it had been run exclusively with internal beams, but when the dees were designed provision was made for the subsequent mounting of an internal d.c.-deflector in one of the dees and during the reassembly of the dees the deflector is being installed.

The machine is housed in an underground hall, resting directly on rock and surrounded on all sides by rock, clay and earth. On the top it is shielded by a water pond two metres deep. The control room is in a three-storey building above ground, and the connexion between the building and the cyclotron hall is via a stairway or a lift to the bottom of a shaft from which a corridor leads to the hall. A removable 150-cm. concrete thick wall partly closes the corridor, leaving an opening 140 cm. broad which can be closed by a concrete door weighing 35 tons. The first article contains full details together with drawings and photographs of the building; the magnet; the radiofrequency tank and dee systems; and the ion-source of the cyclotron. In the second article the techniques used in the work on heavy-ion acceleration in the cyclotron together with some results of the investigation of the energy-distribution for $^{12}C^{4+}$ ions are outlined. It is shown that the distribution contains a low-energy component in addition to the higher-energy peak of the ions. Other applications of the accelerated heavy-ions, in particular for the production of transuranium elements, are briefly mentioned.

DAILY FOOD CONSUMPTION BY SOUTH AFRICAN UNIVERSITY STUDENTS

It has been the practice of the Department of Physiology of the University of the Witwatersrand to request students, as part of their physiological training, to keep a daily record of their food consumption over a defined period of time. The records from one year's class form the basis of a preliminary report by Sonia E. Walker; but it is hoped that data accumulating over several years will afterwards be analysed, and will give some indication of the dietary trends in this student section of the community (*South African J. Med. Sci.*, 24, December, 1959).

The food consumption-levels of the students investigated are similar to those reported from other parts of the world. In a survey of dietary levels of households in the United States, the average consumption per person per day was found to be 2.760–3,260 calories, 87–115 gm. protein and 133–161 gm. fat. The share of total calories derived from carbohydrate was 43 per cent, from protein 13 per cent, and, from fat, 44 per cent. A more recent report based on the estimation of apparent civilian consumption *per capita* per day in the United States gives mean daily intakes of 3,160 cal., 96 gm. protein, 378 gm. carbohydrate and 144 gm. fat. In the United Kingdom a similar estimation of food consumption per head of civilian population per day gave 2,890 cal., 380 gm. carbohydrate, 112 gm. fat, and 90 gm. protein.

The mean daily fat intake of the male group of South African students was 110 gm. This is considerably less than the average American intake, but similar to the daily intake in Britain. The mean protein consumption of the male medical students is 102 gm. per day, which is higher than that found in the United States or Britain.

For practical purposes, the majority of the medical students could probably be classed as sedentary workers, as a large part of their day is spent in sitting in lectures and in dissecting rooms, or in doing laboratory work. Recommended daily allowances for young males doing sedentary work range from 2,400 cal. and 70 gm. protein according to American standards to 2,250 cal. and 66 gm. protein according to British standards.

The present study showed a marked sex difference in food intakes between the male and female students. This is in agreement with observations made on college men and women in the United States, where the men were found to consume more meat, milk and cereals than the women students.

The calorie intake of the Johannesburg women students was slightly less than that found in a group of American students of comparable age, body-weight and height.

DISTRIBUTION OF ATMOSPHERIC OZONE; A PRELIMINARY ANALYSIS OF SOME INTERNATIONAL GEOPHYSICAL YEAR OBSERVATIONS

By J. MacDOWALL

Royal Society International Geophysical Year Expedition, c/o The Royal Society, Burlington House, London, W.1

THE three years of total atmospheric ozone observations at Halley Bay (75° 31′ S., 26° 37′ W.) do not fit into the world-wide picture of the ozone distribution first measured by Dobson[1] from 68° N. to 44° S. Maximum amounts of ozone are not observed until the equivalent of 2–3 months after the seasonal maximum in high northern latitudes, and the highest values observed in the southern hemisphere are lower than in the north.

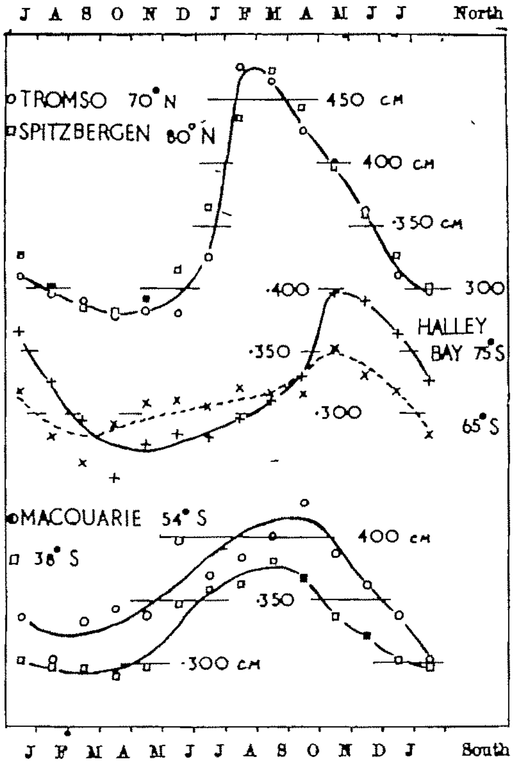

Fig. 1. Shows that the type of seasonal variation of total ozone at Halley Bay is also discernible at Argentine Islands (65° S.), and the seasonal variation at both stations differs greatly from the variation found at high-latitude northern stations

Fig. 1 shows that the type of seasonal variation at Halley Bay is also present, but much less definite, ten degrees to the north at Argentine Islands; the seasonal variation of ozone at both stations differs greatly from the variation found at high-latitude northern stations. International Geophysical Year observations of total ozone at Macquarie Island, Melbourne, and Brisbane show a more 'normal' seasonal variation.

The International Geophysical Year observations from twelve northern and five southern stations are used in Fig. 2 to illustrate the marked difference

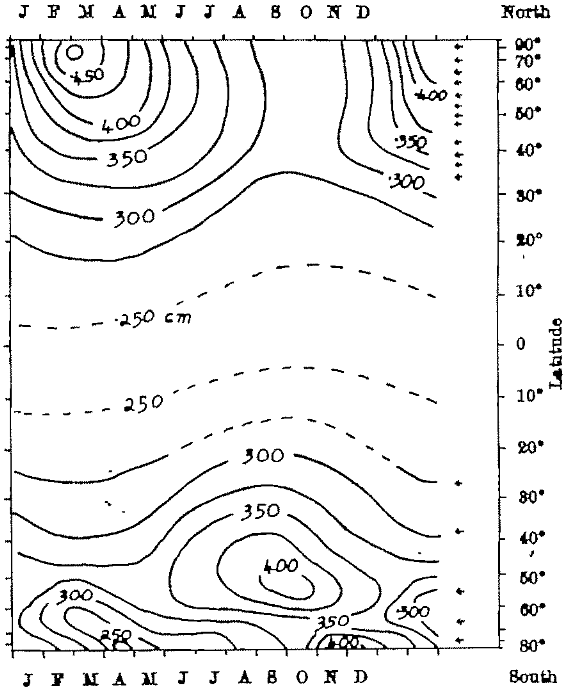

Fig. 2. Smoothed monthly mean results of ozone measurements from seventeen stations illustrating the marked difference between the hemispheres in the seasonal variation of the total quantity of atmospheric ozone

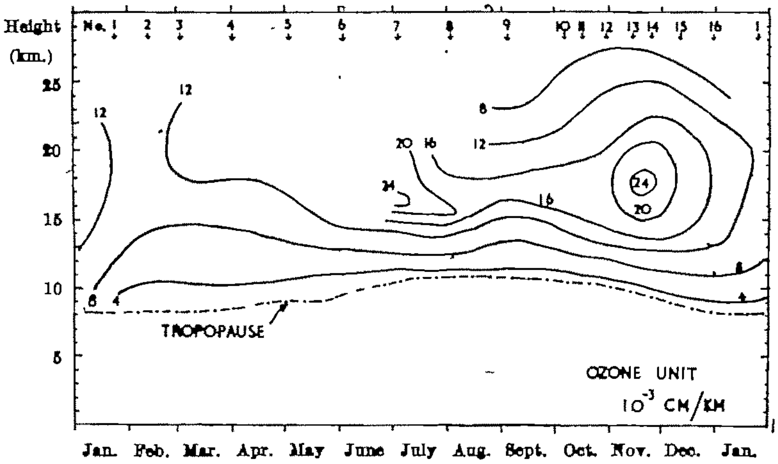

Fig. 3. Smoothed results of sixteen ozone sonde ascents showing the seasonal change in the form of the ozone layer over Halley Bay

between the hemispheres in the distribution of atmospheric ozone at latitudes higher than 55°. The small arrows on the right of the diagram indicate the latitude of the seventeen stations; ozone values for low latitudes, shown by dotted lines, are chiefly due to the work of Normand[2]. There is a close similarity between the hemispheres in low latitudes, but south of 55° S. completely new features of the ozone distribution are revealed, particularly during July–September (compare with the ozone distribution during January–March in the north). In these early spring months the amount of ozone in the north increases very rapidly with latitude, but in the south least ozone is found at high latitudes.

Upper air conditions are well known to be related to the total amount of ozone[3]. Short period fluctuations of 3-day mean values about the 10-day running mean of air temperature and pressure are related to short-period fluctuations of ozone at Halley Bay, but they are less closely related than in south-east England. However, at Halley Bay, 10-day running mean of air temperature and pressure are found to bear little or no relation to the total amount of ozone, whereas in south-east England these measurements are closely related.

During 1958 a series of sixteen chemical ozone sondes were flown from Halley Bay; the sonde was designed by Dr. A. W. Brewer[4] at the Clarendon Laboratory, Oxford, to fit on a standard Kew type radio sonde as used by the Meteorological Office, London. The results of these flights are used in Fig. 3 to draw a smoothed height/time cross-section of ozone concentration over Halley Bay. Apart from the intrinsic interest of these soundings it is of importance to notice at the moment how they confirm the lateness (compared with high northern latitudes) of the ozone maximum at Halley Bay. The great success in the operation of this somewhat temperamental instrument was largely due to the skill of Mr. J. A. Smith, who joined the Meteorological Group at Halley Bay for 1958.

I take this opportunity to thank my colleagues at the Royal Society Base for their co-operation which made the ozone work successful, Mr. J. Farman of the Falkland Island Dependencies Survey, for provisional International Geophysical Year daily values of total ozone at the Argentine Islands, and Dr. G. M. B. Dobson for the great benefit of his advice.

This work formed a part of the programme of the British National Committee for the International Geophysical Year; a full discussion of the results will be published in due course[5,6].

THEORY OF AURORAL STRUCTURES

By E. R. HARRISON*

Atomic Energy Research Establishment, Harwell

THE varied structures of the visual auroræ present problems in many branches of physics. In this discussion the subject is simplified to some extent by ignoring so far as possible such questions as where the auroral streams come from, how they gain their energy, and what are the excitation mechanisms. On the other hand, the present treatment collects together some of the properties, such as stability, peculiar to beams guided by the geomagnetic field prior to their entry into the denser regions of the atmosphere. It turns out that stable beams are possible provided they are thin in cross-section. The break-up of arcs into rayed structures can, it appears, be explained by the conditions governing the growth of electrostatic oscillations in the streams. It seems reasonable that quiescent arcs and rays are equilibrium structures, free at least from any gross forms of instability, whereas many of the transient effects of auroral phenomena are the result of unstable streams.

Auroral displays[1] often begin with quiet, homogeneous arcs extending distances of several thousand kilometres along parallels of geomagnetic latitude. A striking feature of many of the arcs is their thinness; Elvey[2] reports that on one occasion an arc had an estimated thickness of 0·25 km. Frequently several arcs are close together and as many as six have been observed in a distance of 25 km. along a geomagnetic meridian. Later in the display the arcs tend to brighten and then disrupt into rayed structures. Later still, the display may change to pulsating

* Temporarily on leave at CERN, Geneva.

surfaces and flaming auroræ. Apart from the amorphous and relatively transient forms of auroræ, the two basic types of structure in any display are the arcs and the rays[3]. They occur either independently or together in various combinations. Both types extend upwards along the geomagnetic lines of force. Arcs extend vertically for approximately 50 km. and seldom more than 100 km. Rays, however, can have heights of several hundred kilometres, and also diameters of less than 0·5 km. Doppler shifted hydrogen lines are observed in homogeneous arcs[4] (but so far not in rays) and indicate maximum incoming proton velocities of at least 3×10^8 cm.sec.$^{-1}$. In the arcs it seems that the excitation is produced partly by protons, whereas in rays the excitation is primarily by electrons[5].

Commencing with the idea that the beams responsible for producing the auroræ may consist of streaming plasma, one finds that in the absence of electric fields the electrons are rapidly eliminated and the plasma is converted into an ion beam. Let H_0 be the geomagnetic field strength where the plasma is injected at an initial temperature T_0. With no collisions, the magnetic moments are invariant, and the mean transverse kinetic energy increases as $kT_0 H/H_0$ at the expense of the longitudinal kinetic energy, as the particles approach the Earth. In a streaming plasma the electrons have a relatively small kinetic energy and they are therefore brought to rest more quickly than the ions. Thus, if kT_0 is of the order of 10 eV., and protons have initially an energy of 10^5 eV., the electrons are arrested when $H \simeq 5H_0$, and the protons when $H \simeq 10^4 H_0$. Assuming that injection occurs at a distance of 10 Earth radii, the plasma is converted into a proton beam at 6 Earth radii, and at the Earth's surface the protons (assuming no collisions) have lost 10^4 eV. When, however, the plasma is density-modulated into bunches, either by spatial or time growing oscillations (see below), the associated electric fields do not have to be large to trap and drag along some of the electrons and increase their transverse kinetic energy at the expense of the energy of the protons. This mechanism may account for some of the energetic electrons found in the auroral zones[6] and in the outer Van Allen belt[7], particularly if the initial transverse energy is larger than that assumed above.

The beams producing the quiescent arcs and rays are evidently guided in a rigid manner by the geomagnetic lines of force. An analysis of the problem shows that there is lateral stability when the Maxwell stress tensors of the geomagnetic field exceed the stress tensors of the self-fields and of the beam itself[8]. Neglecting for the moment the self-fields, this requires that:

$$H^2/4\pi > n_b^+ m_b^+ v^2 \qquad (1)$$

where n_b^+ is the number density and m_b^+ the mass of the ions in the beam, and v is the velocity component parallel to the geomagnetic field H. When the 'tension' of the geomagnetic lines of force is greater than the 'negative tension' of the momentum flux, as given by (1), the beam is hydromagnetically stable. The upper atmospheric density is comparable with or greater than the beam density, and when (1) is not satisfied the Alfvén phase velocity has complex values and the beam is unstable against transverse perturbations[9].

From (1) it follows that the stress tensors of the self-magnetic field components are small compared with $H^2/4\pi$ provided the beams which produce the rays have a radius d, and the beams which produce the arcs a semi-thickness d, given by:

$$d < \delta_b \qquad (2)$$

where $\delta_b = (m_b^+ c^2/4\pi n_b^+ e^2)^{1/2}$ is the collision-free penetration depth of an electromagnetic field for the beam ions. In the case of protons $\delta_b = 2 \times 10^2 n_b^{-1/2}$ km.

Condition (2) is also necessary if the Larmor radius of the beam ions in the transverse self-magnetic field is to exceed the beam radius. This has been shown elsewhere[10] for cylindrical beams in terms of Budker's parameter $\nu = (d/2\delta_b)^2$, and it seems that for non-relativistic speeds (2) is necessary for a streaming type motion, whereas $d > \delta_b$ applies for plasmas in which the relatively small drift motions are maintained by electric fields. For constant-speed ions the ratio d/δ_b varies at most by $\sqrt{2}$ in any beam following the geomagnetic flux lines; thus if (2) is true at one point, it is also approximately true for all points of a constant speed beam. In spite of both (1) and (2) instabilities may still occur, particularly in arcs, due to transverse force fields producing drift motions[11]. For example, it has been suggested that drift motions are responsible for the folding of arcs into draperies[12].

Using the plasma parameter β, defined as the ratio of the thermal and magnetic pressures, (1) is equivalent to $\beta < 2kT/m_b^+ v^2$. Beams with energy sufficient to penetrate only to a magnetic field strength H are initially stable if $\beta < H_0/H$, provided the magnetic moments are invariant. One notices that the beam ions have a mean Larmor radius in the geomagnetic field of $\delta_b \beta^{1/2}$.

We first consider the possibility that the incoming proton beams proceed directly from a large-scale source or stream external to the geomagnetic field. If a stream of particles is incident on regions of the geomagnetic field of strength H_0, and we assume that the convergent flux lines are parallel to the stream velocity, then by Busch's theorem[13] it is found that if (1) is satisfied, then (2) is also satisfied. In one particular model one imagines that tongues of plasma from the solar wind are injected into the unstable outer surface of the geomagnetic field[14]. One might tentatively extend such a model by suggesting that the outer Van Allen belt contains the particle injections which have failed, due to beam instabilities, to produce an immediate auroral effect; such instabilities could be responsible for the energetic electrons found in the belt. It has been suggested[15] as an alternative possibility that auroral beams originate from regions within the Earth's magnetic field, as, for example, the outer Van Allen belt mentioned above. The difficulty with this suggestion is that there is no evidence[7] of the trapped energetic protons at distances of several Earth radii which are at least necessary for the quiet arcs.

So far what has been said applies more or less equally for the beams which produce both the ray and arc type structures. However, the possibilities are strong that the situation is different when one turns to the subject of electrostatic oscillations in beams passing through a plasma. Because of the long-range Coulomb forces, initial density fluctuations under certain conditions can grow into bunches, and the coherent interactions lead to a rapid loss of momentum from the beam[16]. In the present treatment it is sufficient to consider only those coherent interactions in the beam which occur high above the auroral display. These interactions will determine whether the beam survives to contribute to the auroral display, and whether the beam will produce an arc or a ray. At lower altitudes, approaching the ionosphere, the electron density rises to a value which makes it extremely unlikely that any non-relativistic beam of electrons or protons larger in radius than a few metres is stable. As a result the energy of the incident streams is converted into fluctuation and drift energy of the atmospheric electrons. Radio studies of the aurora[17] have shown for some time that there are electron density fluctuations having in some cases the form of bunches elongated along the magnetic field. These fluctuations have been attributed principally to atmospheric turbulence. In the present discussion it is suggested that the coherent bunching observed in the ionospheric and auroral regions are possibly the result of incoming particle streams.

From the electromagnetic equations, the equations of motion and continuity, we have:

$$\nabla_{\perp}^2 E_z + k_z^2 \varepsilon E_z = 0 \qquad (3)$$

$$1 - \frac{\omega_b^2}{(\omega - k_z v)^2} - \frac{(\omega_e^+)^2 + (\omega_e^-)^2}{\omega^2} = \varepsilon$$

where E_z is the longitudinal component of the electric field, $k = (k_z^2 + k_{\perp}^2)^{1/2}$ is the wave number, and ω_b and ω_e are the plasma frequencies for the beam and plasma, respectively. It is assumed that only longitudinal oscillations occur. Interactions between the beam and the stationary atmospheric electrons is complicated by the fact that there is momentum transfer and the moving electrons in turn interact with the atmospheric ions. Comparing the rates of momentum transfer (Ohkawa, T., privately communicated) one finds by an approximate treatment that the electrons are dragged along at a speed of $v n_b / n_e$, which is of the order of 10^4 cm.sec.$^{-1}$. But this method neglects Landau damping due to the thermal motion of the electrons and the velocity spread of the beam. It has been shown[18] that an electron stream interacts with stationary ions when it has a velocity exceeding its mean random speed, or in this case when $v n_b / n_e > (2kT/m^-)^{1/2}$. This requires an electron thermal energy of less than 10^{-3} eV. The thermal energy is certainly greater and at high altitudes might be as large as 10 eV., and in this case beam interactions with the electrons can be neglected.

Consider first the case of short transverse wave-lengths, given by $k_{\perp} d > 1$. Using the dispersion equation obtained from (3) one finds that there are spatially growing waves (k_z is complex) for $k_z < k_{\perp}$, and time growing waves (ω is complex), when:

$$k_{\perp} < \frac{1}{v}\{\omega_b^{2/3} + (\omega_e^+)^{2/3}\}^{3/2} \qquad (4)$$

and there is no velocity spread in the beam. At distances of several Earth radii the atmospheric ion density is possibly of the order 10^3 cm.$^{-3}$, and the beam density is, say, of the order 1 cm.$^{-3}$, and therefore $\omega_e^+ > \omega_b$. It follows from (4) and the assumption that $k_{\perp} d > 1$ that a sufficient condition that there are no instabilities is:

$$d < \frac{v}{c}\,\delta_e^+ \qquad (5)$$

where $\delta_e^+ = c/\omega_e^+$. For $v/c \sim 10^{-2}$ the beams must have a semi-thickness or radius of $d < 0 \cdot 2$ km. When this condition is not fulfilled the beam loses its momentum in a distance:

$$L \simeq \frac{\lambda}{2\pi}\left(\frac{\omega_e}{\omega_b^+}\right)^{2/3} \ln \Lambda \qquad (6)$$

where λ is the wave-length of the disturbance, and the logarithmic term has a value between 10 and 100 and depends partly on the mean square fluctuation $[(\Delta n/n)^2]$. The effect of a large velocity spread[18] in the beam is difficult to assess without some knowledge of the distribution function. The growth-rate of instabilities will be reduced and possibly there will be a relaxation in the stability condition (5).

Condition (5) is sufficient for stability when $k_{\perp} d > 1$. If we regard the transverse standing waves as dividing the beam into raylets of diameter $k_{\perp} d = 1$, then (5) is the necessary condition for stability in each raylet. At low altitudes the electron interaction cannot be neglected and the stability condition becomes:

$$d < \frac{v}{c}\,\delta_e^- \qquad (7)$$

and for $n_e^- \sim 10^6$, this gives $d < 5$ cm. Thus, practically all beams lose energy due to coherent interaction as they approach the ionosphere.

For long wave-lengths the electric fields are no longer confined to the beam and the appropriate boundary conditions must be used for solving (3). As a result, the frequencies are reduced by $(k_z^2 d/k_y)^{1/2}$ for sheet beams which produce arcs when $k_y d < 1$ (where k_y is in the transverse direction along the geomagnetic longitude), and approximately by $k_{\perp} d$ for cylindrical beams which produce rays when $k_{\perp} d < 1$. The conditions that there are no time and space growing waves, and therefore the beams are stable, are:

$$\begin{aligned} &\text{(arc)} \qquad d < \frac{v}{c}\,\delta_e^+ (k_y d)^{1/2} \\ &\text{(ray)} \qquad d < \frac{v}{c}\,\delta_e^+ \left\{\frac{2}{\ln(1/k_y d)}\right\}^{1/2} \end{aligned} \qquad (8a,\ b)$$

For ray beams (8*b*) is sensibly the same as (6) with the exception of the logarithmic dependence on $1/k_y d$. Arc beams, however, are always unstable for sufficiently long transverse wave-lengths. Thus, when an arc beam becomes unstable the transverse standing waves grow rapidly, and for short transverse wave-lengths for which $k_y d \rightarrow 1$ the stability is eventually determined by the ray condition (8*b*).

There are, therefore, a number of elementary conditions necessary for the stability of auroral beams which are broadly covered by (1), (2), (5) and (8*a*, *b*). Presumably, in the early stages of an auroral display the beams have a low density and there is no serious growth of coherent interaction at high altitudes. A diffuse source ejecting particles towards the Earth will produce thin homogeneous arcs extending along the geomagnetic latitudes. During the auroral display the beam density apparently increases and the arc beams become unstable; there is then a loss of beam energy. Transverse density variations in the arc beams, however, can lead to the formation of ray beams, which are more stable. According to this treatment the arc is the more fundamental of the two types of structure, and the presence of rays must indicate that arc type beams are arrested in regions possibly high above the auroral display. In these regions there are considerable fluctuations which modulate the down-coming rays, and at lower levels these fluctuations grow spatially, as in a travelling wave amplifier, due to an increase in the density and a reduction in the temperature of the atmospheric electrons. The oscillations in the ray beams may account for their luminous length, the loss of proton energy due to the atmospheric electron drag is possibly a reason why no hydrogen lines are observed, and the increased energy of the electrons[19] which are excited or dragged down by the beams may also explain the electron impact excitation which predominates in ray structures.

Acknowledgments are gratefully made to Tihiro Ohkawa for a number of informative discussions on plasma and beam oscillations, and to Lloyd Smith for discussions and comments on the treatment outlined in this paper.

INFRA-RED SPECTRA OF AMINO-ACIDS AND RELATED SUBSTANCES IN WATER

By PROF. FRANK S. PARKER and PROF. DONALD M. KIRSCHENBAUM

Department of Biochemistry, State University of New York, Downstate Medical Center, Brooklyn, New York

ADVANCES both in infra-red instrumentation and in the availability of barium fluoride windows for the manufacture of infra-red cells to contain aqueous solutions stimulated us to undertake a systematic investigation of infra-red spectra of various small molecules of biological importance, including amino-acids and related amines. Until recently, most infra-red spectrophotometric measurements on compounds of biological interest have been made in mulls, in films, in organic solvents, or in potassium bromide pellets[1]. However, following Coblentz's[2] early work with water, Gore *et al.*[3], Blout[4], and others have used aqueous solutions for infra-red studies of certain materials. The present article contains some of the results of our work on amino-acids and derivatives.

Infra-red spectra were recorded as described in a previous publication[5]. Concentrations are recorded in the legends to the figures.

Fig. 1 shows the spectrum of water between 950 and 1,600 cm.$^{-1}$, and typical examples of solubility effects in the aliphatic amino-acids. It is seen that saturated solutions of glycine and alanine have distinctive spectra. The solubility of glycine[6] is 25 gm. per 100 gm. of water at 25°; the solubility of L-alanine is 16·5 gm. per 100 gm. of water at 25°. These amino-acids still show distinctive spectra at 5 per cent concentrations in water; thus glycine still shows distinctive absorption bands at 1,404, 1,319 and 1,124 cm.$^{-1}$; and alanine at 5 per cent concentration still shows the distinctive bands at 1,408, 1,351, 1,299, 1,212 and 1,105 cm.$^{-1}$, among others.

Fig. 2 shows, however, that saturated solutions of valine, leucine and isoleucine have very few distinctive absorption bands, as one would expect from their solubilities. The solubility of DL-valine is 7·1 gm. per 100 gm. of water at 25°; the solubility of L-leucine is only 2·2 gm., and the solubility of L-isoleucine is only 4·1 gm.

Fig. 3 shows the spectra of proline, serine, threonine and hydroxyproline. The effects of changing the structure from a primary hydroxy compound, serine, to a secondary hydroxy compound, threonine, can be seen. Zeiss and Tsutsui[7] have shown that in alcohols with a saturated chain, a band appears between 1,075 and 1,010 cm.$^{-1}$ for primary alcohols. On the other hand, in secondary alcohols the band

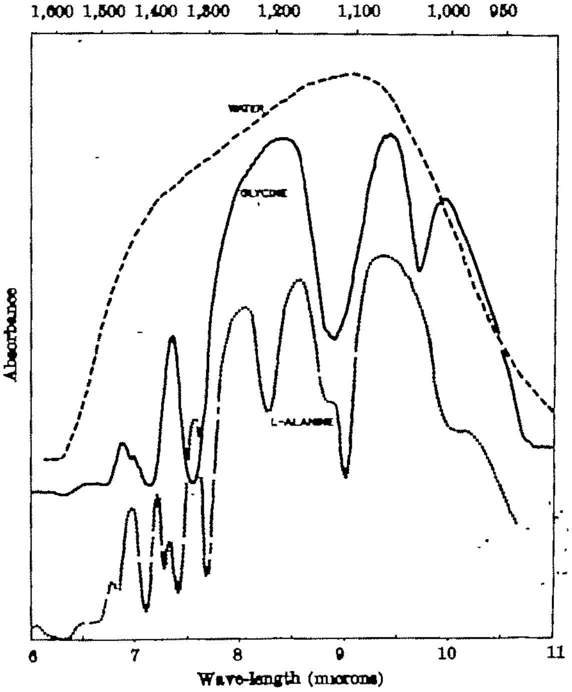

Fig. 1. Spectra of water, glycine and L-alanine. The amino-acids were in saturated solutions. Barium fluoride cell, 0·05 mm. thickness

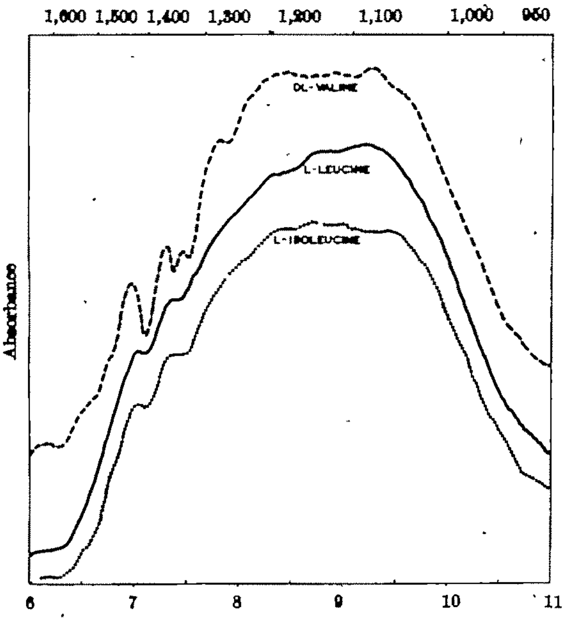

Fig. 2. Spectra of DL-valine, L-leucine and L-isoleucine in saturated solutions

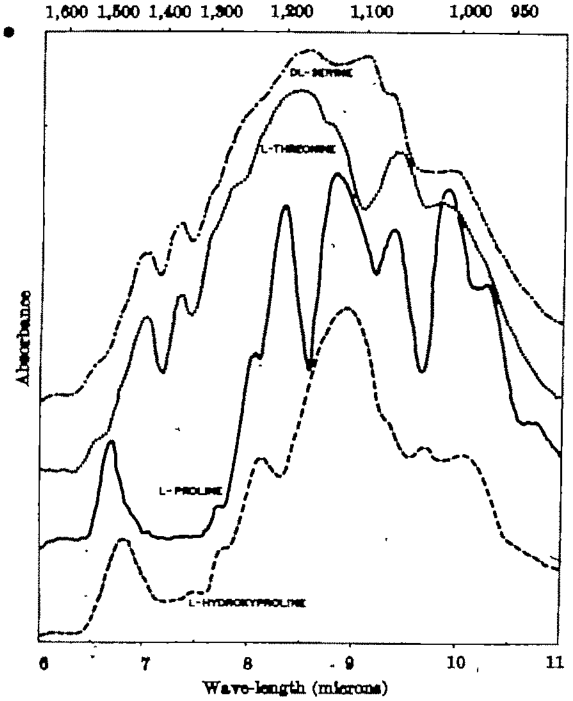

Fig. 3. Spectra of DL-serine (5 per cent solution); L-threonine (5 per cent solution); L-proline (saturated solution); and L-hydroxyproline (saturated solution)

appears between 1,119 and 1,105 cm.$^{-1}$. It is of interest, therefore, that serine has an absorption band at 1,020 cm.$^{-1}$, which is in the range for primary alcohols; and threonine absorbs at 1,100 cm.$^{-1}$, which is in the range for secondary alcohols. However, hydroxyproline, which contains a secondary —OH group on a cyclic imino-acid, does not show absorption where one would expect a secondary alcohol to absorb, namely, from 1,105 to 1,119 cm.$^{-1}$; rather, there is a band at 1,205 cm.$^{-1}$.

It is of interest to note the distinctive differences between the spectra of the imino-acids proline and hydroxyproline, particularly the band in proline at 1,163 cm.$^{-1}$. These differences can perhaps be used to advantage in the examination of the conversion of proline to hydroxyproline, an important process in the biosynthesis of collagen[8]. Although saturated solutions of proline and of hydroxyproline were used, 5 per cent concentrations of these amino-acids can still be differentiated.

Aspartic acid is known to undergo decarboxylation of either the α- or the ω-carboxyl group to form

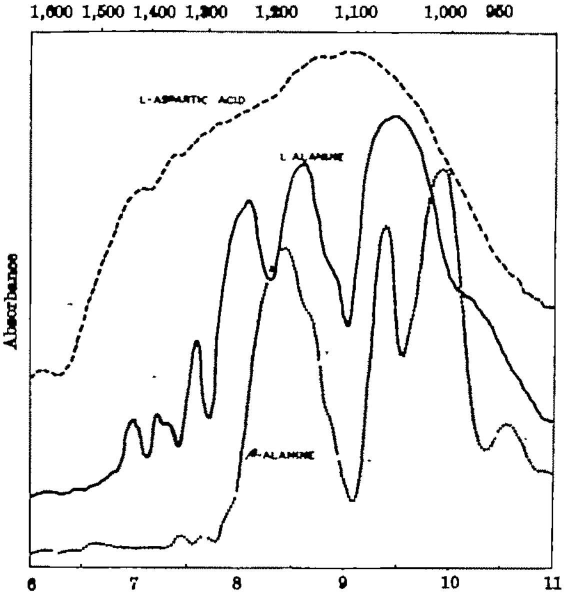

Fig. 4. Spectra of L-aspartic acid, L-alanine and β-alanine in saturated solutions

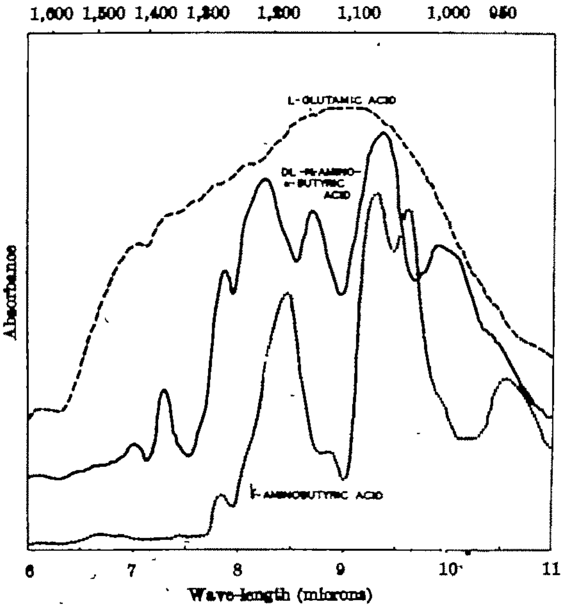

Fig. 5. Spectra of L-glutamic acid, DL-α-aminobutyric acid, and γ-aminobutyric acid in saturated solutions

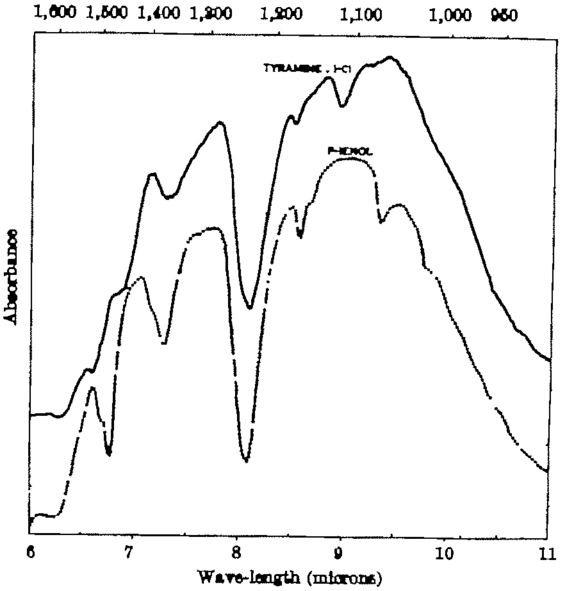

Fig. 6. Spectra of tyramine hydrochloride (10 per cent solution) and phenol (7 5 per cent solution)

either β-alanine or alanine. Examination of Fig. 4 shows that it may be possible to follow such changes using infra-red techniques. There are distinct differences between the spectra of aspartic acid, L-alanine and β-alanine. Infra-red techniques would thus permit one to deduce which end of aspartic acid has lost its carboxyl group. Similarly, in Fig. 5 are shown the spectra of L-glutamic acid, DL-α-aminobutyric acid and γ-aminobutyric acid. Either of the aminobutyric acids can be obtained by decarboxylation of glutamic acid. It is thus possible to distinguish between glutamic acid and either of these decarboxylation products by their infra-red spectra.

With the aromatic and heterocyclic amino-acids, the problem of low solubility of the dipolar ionic form again appears and this renders the demonstration of distinctive spectra difficult. However, the decarboxylation products display distinctive spectra; for example, tyramine (Fig. 6), which is the decarboxylation product of tyrosine, displays a distinctive spectrum as the hydrochloride. Comparison of this spectrum with that of phenol shows that the main absorbing group in tyramine between 950 and 1,600 cm.$^{-1}$ is the phenolic moiety. Tyrosine was too insoluble to study.

The absorption characteristics of many other amino-acids, related homologues and decarboxylation products are being investigated in our laboratory and will be reported elsewhere[9].

A preliminary report of this work was presented before the American Society of Biological Chemists in Atlantic City, New Jersey (*Fed. Proc.*, 18, 299; 1959).

A HYPOTHESIS OF CONTRACTION IN STRIATED MUSCLE

By Dr. M. SPENCER and Dr. C. R. WORTHINGTON

Medical Research Council Biophysics Research Unit, Wheatstone Laboratory, King's College, London

WE wish to suggest a mechanism by which the system of sliding filaments in striated muscle, proposed by H. E. Huxley and Hanson[1] and by A. F. Huxley and Niedergerke[2], might be caused to exert a contractile force during excitation. The mechanism is probably also applicable to those smooth muscles which have a double array of filaments[3]. It relies on electrostatic forces between sites on the actin and myosin filaments, and does not necessarily require mechanical linkage between them. It does not involve contraction or folding of the filaments, and thus differs from previous models using electrostatic forces[4].

The mechanism was suggested by the results of recent work by one of us[5] on X-ray diffraction from striated muscle fibres. The results showed that, in addition to orders of the previously observed axial spacing of 410 Å. attributed to actin, orders of an axial spacing of 435 Å. could be seen which were attributable to myosin. The arguments on which this assignment is based have been presented elsewhere[5]. The spacings are significantly different, and can be observed together in the same X-ray diffraction pattern, and in both the wet and the dry state. Work on living muscle is in progress in this Laboratory.

Basic Assumptions

Let us assume that excitation of a striated muscle is ultimately transferred to the actin filaments where they meet the Z-lines. (There is evidence that excitation is transferred from the surface membrane to structures called triads in the sarcoplasmic reticulum[6]. In frog muscle the triads lie opposite each Z-line; in certain other muscles there are two per sarcomere, displaced from the Z-line by a quarter of the sarcomere length.) The terminology is illustrated in Fig. 1. Suppose also (in common with Szent-Györgyi[7]) that the actin and myosin filaments are, prior to stimulation, mutually repelling each other. The repulsion is assumed to be between sites on the filaments which carry like electrostatic charges. The sites are assumed to be spaced at 410 and 435 Å. along the actin and myosin filaments respectively. It seems likely that the sites on either the actin or the myosin filaments, or on both, are really projections from them. Electron micrographs of striated muscle show 'cross-bridges'

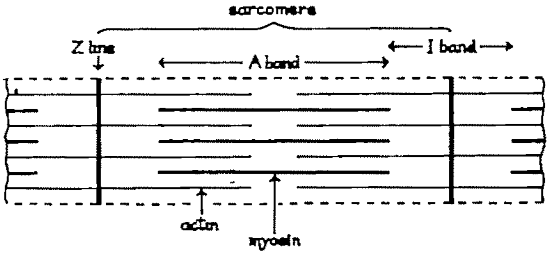

Fig. 1. Diagram of the arrangement of molecular filaments in a striated muscle fibre, according to Hanson and Huxley During contraction the actin and myosin filaments slide past each other

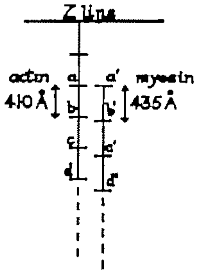

Fig. 2. Diagram of two filaments in a sarcomere, showing proposed sites of electrostatic charge. The difference in spacing has been exaggerated. Sites on the actin filaments are regularly spaced along their length at 410 Å. apart; myosin sites are spaced at 435 Å.

spaced at about 400 Å. which appear to originate from projections on the myosin filaments[7].

Let us now suppose that the excitation transmitted across a Z-line sets off a pulse of charge reversal which travels down the actin filaments so that successive sites on each filament are momentarily given an opposite electrostatic charge. (The idea that some change in properties is propagated down the filaments is not new.) The mechanism by which this could happen is, of course, quite hypothetical at present. We believe that it might be a charge transfer of the type envisaged by Szent-Gyorgyi[8]. A rough parallel may be drawn with the passage of a pulse down an electrical transmission line. Each site carrying a reversed charge would be attracted to whichever sites on the adjacent filaments were nearest to it.

Consequences of the Hypothesis

(*a*) ***Free contraction.*** Consider the effects on only two filaments, one of actin and one of myosin, of a pulse of charge-reversal travelling down the actin filament (Fig. 2), when the myosin is free to move relative to the actin. Assume, for the sake of argument, that the first charged site a' of the myosin lies initially in register with a site a on the actin. When the charge on a is reversed, there will be no axial force on the myosin filament. However, when the charge-reversal is transferred to b there will be an axial force, upwards in the diagram, on site b'. This would also be true for reversal at sites c and d. If the myosin filament was prevented from responding to the upward force, the charge-reversal at sites farther down the actin would give an opposite force. Since, however, the myosin is free to move, reversal of charge on b will cause movement of the myosin until b and b' are in register. The distance between c and c' is then the same as that originally separating b from b'. If the movement is repeated at each transfer of charge, there will be a continuous upward movement of the myosin. If a and a' are not initially in register, the first movement may be downwards, but all subsequent movements will be upwards. This movement in one direction only may be compared with that occurring in a unidirectional synchronous electric motor.

(*b*) *Contraction under load.* We do not suggest that, except possibly under conditions of zero load, the contraction of muscle involves the synchronous motion just described. The speed of contraction of a muscle varies with its load, and to explain this with a synchronous mechanism one would need to postulate that the speed of propagation of the charge-reversal was controlled by the rate of contraction. However, a study of the actual arrangement of filaments in striated muscle shows that there is no need to invoke such a process, and we shall proceed on the assumption that the speed of propagation is constant.

We know from structural studies[1,3,7] that each myosin filament in a striated fibre is overlapped by actin filaments at both ends. Consider what happens when pulses travel simultaneously from two successive Z-lines in a myofibril. We assume that the speed of propagation of the impulse to the beginning of each actin filament is much greater than that of the pulse of charge-reversal down each filament (we shall examine this assumption later). An exact prediction of the sequence of events is impossible without a knowledge of the electrostatic field at all points between the filaments. The analysis which follows describes one possible sequence. It is based on the assumption that, if the pulse arrives simultaneously at a and z (Fig. 3a), the myosin filament will adjust its position so that the distance a–a' is the same as z–z'. There will, in the example shown, be a net force pulling the two actin filaments together. Assume, however, that there is 'slip' so that the position is reached later on where the attracting sites on the actin filaments are midway between pairs of sites on the myosin. Sites c and x in Fig. 3a illustrate this condition. If the myosin filament remained stationary while the pulses moved on to sites d and w, there would afterwards be a force pushing the actin filaments apart again. However, when the pulses are at c and x, the equilibrium of the myosin filament will be an unstable one; the filament will tend to jump into one of two positions so that c and x on the actin are in register either with b' and x' (Fig. 3b) or with c' and y' (Fig. 3c). Subsequent transfer of the pulses to

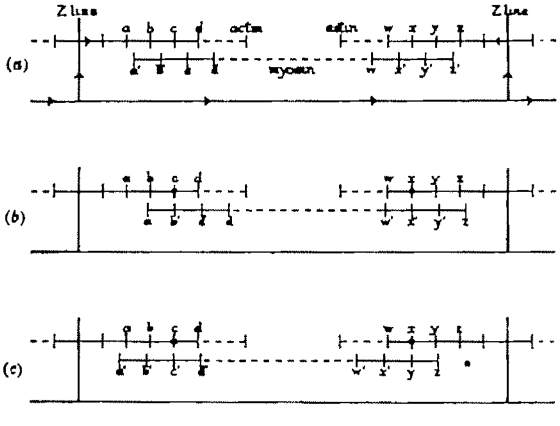

Fig. 3. Three stages in the contraction of a possible model. For explanation see text

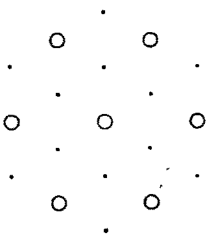

Fig. 4. Arrangement of molecular filaments in a cross-section of the *A* band of a typical striated muscle, as deduced from electron microscopy (ref. 7). Actin filaments are represented by dots and myosin filaments by larger circles

d and *w* will then give rise to forces which still favour drawing together of the actin filaments. We thus see that, provided the myosin is free to make the 'jump' referred to, almost every step in the propagation of the pulses down the actin filaments favours drawing together of the actin filaments. Furthermore, the process is independent of the rate of slip, so that the muscle would exert a tension at all speeds of contraction.

As well as in the special case described above, it can in general be shown that the 'jump' of the myosin filament is essential to the theory; if there was only a steady relative motion of actin and myosin, there would be no net force. However, there is reason to believe that each myosin filament is, in fact, free to move independently. Cross-sections of striated muscle in the *A*-band[7] show that each myosin filament is surrounded by six actin filaments, and is isolated from adjacent myosin filaments (Fig. 4). On the other hand, the fact that every actin filament is adjacent to three others could ensure that the six actin sites which might act on every myosin site were always in register.

(*c*) ***Effect of multiple filaments.*** It is clear from the above description that an individual set of filaments will exert a tension which varies with time. It will at certain instants be zero and, under certain conditions, it may even be negative for part of the cycle. However, a large number of filaments in parallel will, if their jumps are spread out in time, exert an even tension. There is insufficient evidence to decide whether or not all the filaments in a given sarcomere will act in unison. It is not necessary to assume that all the myosin filaments in a sarcomere are identical. A variation among the myosin periods in a typical muscle of only ± 0·5 per cent would spread out in time the jumps of different myosin filaments. The variation of ± 0·5 per cent is less than the experimental error of 1 per cent in measuring the average myosin spacing from a diffraction pattern.

General Properties of the System

A detailed consideration of the expected length-tension and force-velocity curves[10,11] will not be given now. We may, however, note the following properties of the system; some of them are possessed by other possible schemes as well, and have been discussed by previous authors.

(*a*) The maximum tension which the muscle can develop depends on the number of molecular filaments in any one sarcomere, that is, it depends only on the total cross-section of the muscle.

(*b*) The maximum velocity of contraction of the muscle varies as the number of sarcomeres along its length. There is evidence[8,9] that muscles intended for rapid movement often have closely spaced sarcomeres.

(*c*) The isometric tension developed will fall as the muscle is stretched beyond its normal length, because the number of myosin sites overlapped by actin sites will decrease. This means that the number of site interactions per second will also fall (for a given rate of stimulation), and the average force will decrease. A reduction in length will also lead to a fall in tension, for two reasons: first, displacement of fluid by the sliding filaments may increase their separation, and therefore reduce the attraction between sites; secondly, reduction in length will ultimately produce sarcomeres in which the actin filaments have run into each other[7]; this will again result in a drop in the number of interacting sites, and a fall in the tension.

(*d*) The application of an increasing load to the system will lead to an increasing amount of 'slip' from the synchronous motion described, until it just balances the contractile force. It follows that the force-velocity curve must show a decrease in velocity with increasing load.

Thus, qualitatively at least, the expected behaviour of the model is in accord with observation. We have constructed an electromagnetic model which, though crude in that it has only two myosin filaments, illustrates the type of behaviour we have described. It uses coaxial coils to represent the ring of actin filaments around each myosin filament; the latter is represented by a tube containing spaced soft-iron cores. The coils are energized in turn to simulate the passage of the pulse of charge-reversal down the actin filaments.

Discussion

A number of calculations may be made to test whether the assumptions made in the theory are consistent with observations *in vivo*. Examine first the assumption that the passage of the pulse of charge-reversal down each filament takes place at a speed much less than that of the exciting impulse. One way to test this is to compare observed and calculated values for the maximum rate of contraction of a muscle. One would expect that, if our scheme were correct, the maximum rate of contraction of a muscle would correspond with the synchronous motion mentioned earlier. If the velocity of the charge-reversal is v cm./sec., the maximum rate of contraction per sarcomere can be shown to be about 0·12 v cm./sec. In a typical muscle of length 1 cm., having sarcomeres of length 2·5μ, the maximum rate of contraction of the whole muscle will then be 500 v cm./sec. Taking an observed maximum velocity of 2 cm./sec. per cm. length of frog sartorius muscle at 0° C. (ref. 12), the value of v must be about 0·004 cm./sec.—much less than the observed velocity of propagation of the action potential along a fibre, which in many cases exceeds 100 cm./sec. (ref. 13). The assumption that there was this large difference in velocities has not therefore led to a prediction which conflicts with experience. We may note here that the average interval between charge transfers from one site to another will be about 10^{-3} sec.

We may also test whether the calculated value of velocity down the filaments is consistent with the observed frequencies of excitation of muscles *in vivo*. One would expect that, for maximum output from a muscle, the frequency of excitation would be such that one impulse arrived just as the previous pulse of charge-reversal reached the end of the actin filaments. If the frequency was higher than this, the superposition of two pulses on the same set of filaments might lead as often to cancellation of their effects as to reinforcement. (It is of interest to note here that the rate of repetition is in some cases observed to fall when maximum output is not required[13].) If the actin filaments had lengths of 1μ, the time taken for a pulse to travel down them at 0·004 cm./sec. (the velocity calculated above) would be 0·025 sec. The maximum frequency at 0° C would then be 40 impulses/sec. This value is of the right order of magnitude. Calculations based on results obtained at higher temperatures give a higher frequency.

We do not suggest that the nerve impulse transmitted into each *z*-line supplies the energy needed to bring about contraction. We believe that the impulse must trigger a series of reactions which convert chemical energy, perhaps stored in adenosine triphosphate, into electrostatic energy. The theory offers no direct evidence on the reactions involved, and therefore provides no estimate of the heat liberated during contraction.

An important question is whether the theoretical electrostatic attraction between sites can account for the observed tensions developed by living muscle. A typical maximum tension for frog sartorius muscle[10] is 2 kgm./cm.^{2} cross-section. This means that the average force exerted by each myosin filament must be about 3×10^{-5} dyne. If this force is shared between six sites, each of which is opposite an actin site, the average force at each site must be about 5×10^{-6} dyne. The effective force between a myosin site and an actin site is the axial component of the attractive force between them. The component will be zero when the sites are in register. At a large axial separation the component will approach the value of the total force but, due to Debye-Hückel screening, it will be small. Between these two extremes it will rise to a maximum in a way which cannot be predicted without knowing the exact distribution of charges and the ionic conditions in the intervening fluid. In addition to this, there may be large deviations from the simple Debye-Hückel theory under very intense fields. We can, however, make certain assumptions and calculate the maximum component of attractive force between point charges at a given separation.

The most favourable calculation possible is made by neglecting Debye-Hückel screening and assuming a dielectric constant of unity; there are grounds for believing that the relevant dielectric constant may not be as high as that of water. Two sites carrying unit electronic charge would then exert a force of 6×10^{-6} dyne (the average force required) at a separation of about 20 Å. If there were (say) ten electronic charges per site, the separation would be 200 Å. The least favourable calculation is made by assuming the dielectric constant to be that of water, and assuming the Debye-Hückel theory[14] to apply at all separations. The ionic strength, which determines the magnitude of the Debye-Hückel screening, has to be given an arbitrary value; we assume it to be 0·15, a value close to that of human blood serum. The 'thickness' of the ionic double layer[14] will then be about 8 Å. The calculated separation at which unit electronic charges exert the required force on each other is then about 2 Å. This value is, however, so small that the assumptions on which it is calculated cannot be valid, and it is clear that the scheme could not work under these conditions. If, however, there were ten charges per site, the required separation of charges would be 15 Å. This is more of the right order of magnitude, though still somewhat low. For the scheme to be correct we would expect the forces to have appreciable magnitude at distances greater than 25 Å.

It is clear from these calculations that the scheme cannot at present be ruled out on theoretical grounds alone. We may also note that an exact calculation would have to consider the dynamic nature of the process; the attractive force at the beginning of each charge transfer might be greater than that calculated for static conditions, due to the finite time required for equilibrium to be established in the surrounding fluid.

There is one important consequence of the theory which we have not so far discussed. It is that, at any instant during contraction, only a very small percentage (perhaps 4 per cent) of the actin and myosin sites are attracting each other. This implies that the proportion of the biochemist's 'actomyosin' present in contracting muscle will be similarly small, since it seems likely that actomyosin is essentially actin combined with myosin by electrostatic forces. On the other hand, inducement of a charge-reversal of all sites on either actin or myosin would probably cause the filaments to draw together so that they were locked in position by interpenetration of their projections. It seems very likely that such an overall charge-reversal is brought about by removal of adenosine triphosphate from the system[8], since muscles in rigor and glycerol-extracted muscles show the rigidity we have described. The plasticizing role of added adenosine triphosphate and pyrophosphate follows from this idea.

One obvious need in verifying the hypothesis is to extend to the present problem the theoretical work already available on electrostatic forces between charged sites in ionic media[15]. There is, equally, a need to test whether the suggested transfer of charge down the actin filaments does in fact take place. The work of Szent-Györgyi and his associates has shown that this type of process may be vital to many biological systems.

We are indebted to Dr. E. M. Deeley for advice during construction of the electromagnetic model. We would also like to thank Dr. J. Lowy, Dr. J. Hanson and Mr. G. F. Elliott for discussions on the results of muscle research; Dr. M. E. Fisher for advice on theoretical matters; and Prof. J. T. Randall and Dr. M. H. F. Wilkins for encouragement and helpful criticism.

ALTHOUGH the chemical structure of the melanin pigment naturally occurring in mammals is not known[1], much information is available on the mechanism of its formation. Our present knowledge is derived from a study of homogenates or particulate fractions prepared from mammalian pigment cells[2] as well as from histochemical observations on intact cells, with both radioactive and non-radioactive pigment precursors[3]. These studies have established that in mammals melanogenesis is the activity of a specialized type of cell, the melanocyte, which is characterized by the presence of a copper-containing oxidase, tyrosinase, a catalyst responsible for the aerobic oxidation of L-tyrosine, the precursor of melanin, to 5,6-dihydroxyindole. The monomeric 5,6-dihydroxyindole then polymerizes to form a compound of large molecular weight[1]. The melanin polymer is believed to be attached, through its quinone linkages, to amino or sulphydryl groups of the protein matrix of the pigment granule.

Localization of tyrosinase in suspensions of cell particles was first reported by Herrman and Boss[4] in preparations of the ciliary body of the bovine eye. In addition to a "specific catalyst for dopa oxidation", these suspensions also contained two enzymes characteristic of mitochondria, succinic dehydrogenase and cytochrome oxidase. In a study of the Harding–Passey mouse melanoma by differential centrifugation, tyrosinase activity was also reported in the particulate fraction, but the structural elements were thought to be "microsomes or particles the size of microsomes which were formerly part of larger aggregates that were dispersed during the experiments"[2].

In 1949, DuBuy, Woods, Burk and Lackey[5,6] reported that preparations of granules isolated from the Harding–Passey mouse melanoma contained, in addition to melanin, cytochrome oxidase, succinic dehydrogenase and cytochrome *C*, and that they also had tyrosinase activity. These workers arrived at the conclusion that the melanized cytoplasmic particles in the mouse melanomas, which in addition to tyrosinase activity also possessed cytochrome oxidase and succinic oxidase and dehydrogenase activities in considerably varying degree, represent one of several modified forms of mitochondria, but generically mitochondria in any event.

In recent years, several authors have studied the morphology of the melanin granules from various sources in electron micrographs[7]. The melanin granules in human hair bulb appear as dense ovoid or rod-shaped bodies, varying in length from 0·4 to 1·0μ, and in breadth from 0·1 to 0·5μ. In the melanocyte there occurs, distal to the nucleus, an area which contains numerous filamentous mitochondria together with many small vesicles. The centre of this area is believed to be the region where the melanin granules are formed. It is free from melanin granules; but in its periphery there occur structures the size of melanin granules made up of concentric shells upon which variable amounts of dense material are formed; these are considered to be early stages of formation of melanin granules. Both Dalton[8], using Cloudman *S*91 melanoma cells, and Birbeck and Barnicot[7], using human hair bulbs, have concluded that melanin granules and mitochondria differ in size and internal structure. Woods[9] maintains that the melanin granules are melanized mitochondria because of "their high specific activity for enzymes characteristic for mitochondria, their oxygen-dependent staining with janus green B, and the inverse relationship between them and the number of amelanotic mitochondria in the same cells". The need for clarification of this problem is emphasized by Dalton[8], who makes a plea for correlating electron micrographs and chemical data on both melanin granules and mitochondria after centrifugation.

Such an investigation has now been carried out and a separation of mitochondria from melanin granules has been accomplished by the density-gradient

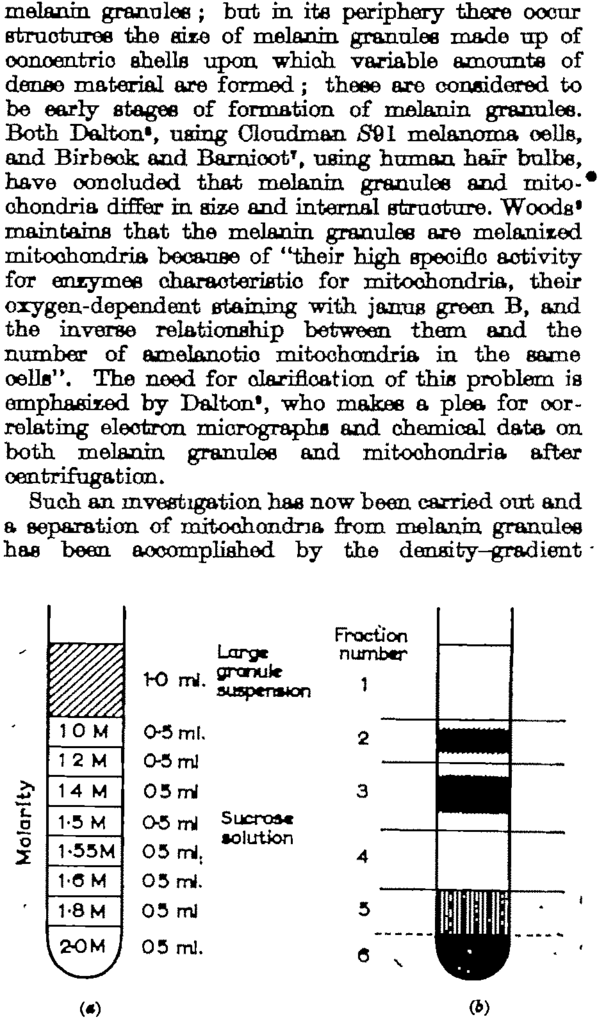

Fig. 1. *a*, Gradient tube before centrifugation; large-granule suspension (in 0·3 *M* sucrose) was added immediately before centrifugation. The gradient was prepared 18 hr. earlier; *b*, gradient tube after ultracentrifugation at 103,000 *g* for 1 hr. The three opaque regions are shown diagrammatically. The places where the tube was cut are also indicated. Fractions numbered 1 to 6

method of centrifugation; the particle fractions thus obtained have been studied by electron microscopy and by biochemical methods. The centrifugation separated two morphologically distinct structures, one of which, the mitochondria, contained succinic oxidase, whereas the other contained the melanin as well as the enzyme tyrosinase.

The 'large-granule' fraction from a Harding–Passey mouse melanoma was isolated by a low-speed centrifugation at 700 *g* for 10 min., followed by a high-speed centrifugation at 11,000 *g* for 10 min. of the low-speed supernatant fluid; the sediment obtained was washed once and suspended in isotonic sucrose solution (0·3 *M*). It was then placed above a density gradient, similar to that used for the separation of mitochondria from amine-carrying granules[10,11]. The gradient used in the present work is shown in Fig. 1*a*. The gradient tubes were centrifuged for 1 hr. at 103,000 *g* in the swinging bucket rotor *SW 39L* of the Spinco ultracentrifuge.

The appearance of the tubes at the end of the centrifugation is shown in Fig. 1*b*. Two narrow bands could be seen, one at the top of the gradient (fraction 2) and a second grey turbid band (fraction 3) between this layer and a relatively clear zone below (fraction 4); near the bottom of the tube a black suspension of particles (fraction 5) and a black pellet could be distinguished. The tubes were cut, using the centrifuge tube cutter kindly presented to the Department of Pharmacology, Oxford, by Dr. E. H. J. Schuster some time ago; a cutter, based on this instrument, has recently been described in a review article by de Duve, Berthet and Beaufay[12]. The positions at which the tubes were cut are indicated in Fig. 1*b* by horizontal lines.

Electron micrographs showed that fraction 2 consisted mainly of cell debris; fraction 3 was an almost pure preparation of mitochondria (Fig. 2*a*). Fractions 5 and 6 contained predominantly melanin granules (Fig. 2*b*). It is apparent that in the density-gradient tube the melanin granules had been separated from the mitochondria; the melanin granules had accumulated in a region of much higher density.

We have determined tyrosinase, succinic oxidase and protein nitrogen content of the various fractions as well as of the large-granule fraction from which they were derived. Tyrosinase was estimated using a 10 : 1 mixture of L-tyrosine and L-dopa as substrates (1·77 μmoles)[13], succinic oxidase by a manometric method[14]. Of the total tyrosinase activity, 94 per cent was recovered in fractions 5 and 6. No tyrosinase activity was found in the mitochondrial layer (fraction 3). Of the succinic oxidase activity, 68 per cent was recovered in fraction 3, 7 per cent in fraction 5, and 4 per cent in fraction 6. Total recovery of succinic oxidase was 83 per cent.

The results of this experiment are given in Table 1. They show that fraction 6 (melanin granules) contains twice as much tyrosinase per milligram of protein nitrogen as the large granules, and that fraction 3 (mitochondria) contains seven times as much succinic oxidase per milligram of protein nitrogen as the large-granule fraction (Fig. 3).

These experiments show that in the Harding–Passey melanoma there exist granules that have the typical appearance of mitochondria in the electron micrographs and contain a high concentration of succinic oxidase, a typical mitochondrial enzyme; these granules are found in the gradient tube in a density layer characteristic of all mitochondria studied whatever their source. In addition, the tumours contained denser granules; these had the typical appearance of melanin granules and they contained the bulk of

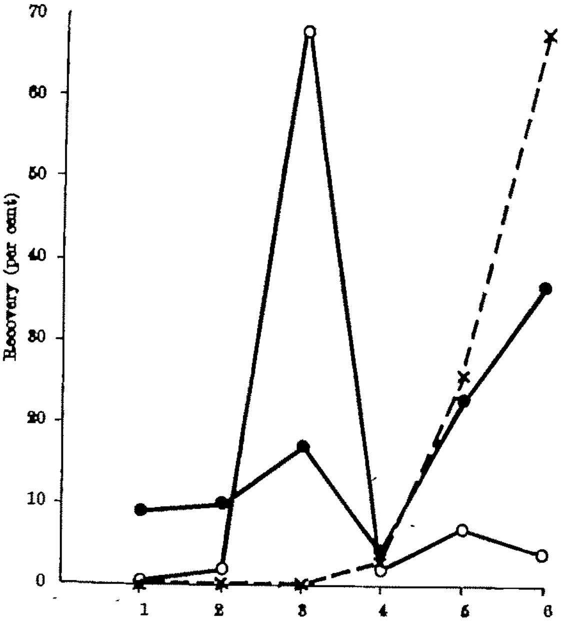

Fig. 3. Contents of fraction 1–6 from density gradient experiment. Percentages are calculated in terms of the amounts recovered in all the fractions. Total recoveries, in terms of contents in large-granule fraction, were: tyrosinase, 96·5 per cent; succinic oxidase, 88 per cent; and protein nitrogen, 100 per cent
×, Tyrosinase; ●, protein nitrogen; ○, succinic oxidase

the tyrosinase activity; they had negligible succinic oxidase activity.

We conclude from our experiments that melanin granules and mitochondria of the Harding–Passey mouse melanoma are distinct cytoplasmic constituents of the melanin-forming cell; each of these constituents is equipped with its own typical enzymes. The method employed does not, by itself, exclude the possibility that melanin granules are derived from mitochondria, but in view of the cytological evidence quoted we see no reason for assuming that such a relationship exists between the two types of structure here described.

We wish to acknowledge support given by a Research Grant from the National Cancer Institute, U.S. Public Health Service, to Drs. Seiji and Fitzpatrick, and by a grant-in-aid from the Royal Society to Dr. Blaschko. In addition, we express our gratitude to J. R. P. O'Brien, head of the Department of Biochemistry (Radcliffe Infirmary), for use of the facilities in his Department.

CRITICAL ENERGY BARRIERS IN THE EXCRETION OF SODIUM

By Prof. E. J. CONWAY, F.R.S.

Department of Biochemistry, University College, Dublin

THE secretion of sodium is considered here chiefly with respect to such large-scale secretion of sodium ions as occurs when frogs' sartorii are immersed in Ringer–Conway fluid containing 120 m*M* sodium and then re-immersed for 2 hr. at room temperature in similar fluid containing 104 m*M* sodium and 10 m*M* potassium[1,2]. It was found under such conditions that the re-immersed muscles lost in the average about 20 m.equiv. sodium per kgm. of the muscle before re-immersion, the average concentration after the first soaking being approximately 59 m.equiv./kgm. (ref. 4).

This type of experiment will for convenience be referred to here as the 120/104/10 procedure, and there will be occasion to refer to others such as the 120/120/10, 104/104/10 and the 120/120/30 procedures.

It was found that there was no significant secretion of sodium using the 104/104/10 procedure[3,4], which was in marked contrast to the results of the 120/104/10 procedure[3]. As a tentative hypothesis it was considered that the over-night immersion in fluid with sodium-level of 120 m*M* in some way stimulated the activity of the sodium pump in the subsequent 2-hr. re-immersion period. But it was found also that the 120/120/10 procedure resulted in no significant excretion of sodium, and this was interpreted in the sense that though the pump was here likewise stimulated, there was an entrance of sodium in the re-immersion period which about balanced the excretion. With such procedure the hypothesis was tested by inhibiting the excretion of sodium either by 2 m*M* iodoacetate or by ouabain (10^{-4} *M*) (Conway, Kernan and Zadunaisky, unpublished work), which had been shown[4] to inhibit fully, or practically so, the net secretion of sodium when using the 120/104/10 procedure. With sodium secretion so inhibited it could be expected that sodium would increase within the muscle, in about corresponding amount. But no appreciable increase of sodium was observed at the end of the 2-hr. period.

It was also shown that the explanation did not lie with osmotic pressure differences in the fluids used

It was then decided to test another hypothesis, namely, that the cause of the marked difference in secretion resulting from the use of the 120/104/10 and the 104/104/10 procedures could arise from the

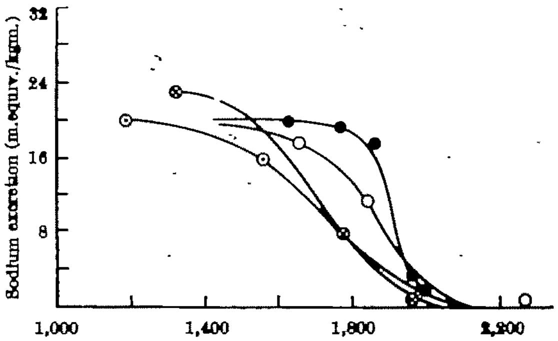

Fig. 1. ●, for series 120/120/10, 120/115/10, 120/104/10, 120/80/10 ; ○, for series 104/104/10, 104/80/10, 104/104/30 ; ○, for anaerobic series, 120/120/10, 120/104/10, 120/104/30 ; ⊗, for 120/120/30, 120/120/60

existence of a critical energy barrier under the conditions. The energy barrier to the secretion of sodium may be written:

$$\frac{dG}{dn} = RT\ln\frac{[Na]_e}{[Na]_i} - E_mF \qquad (1)$$

where n is the number of moles of sodium excreted and $[Na]_i$ and $[Na]_e$ are the concentration of sodium in the fibre water and in the external fluid, E_m being the membrane potential (but the numerical value of $-E_mF$ is positive). If one includes associated movements of potassium or chloride ions, the same equation will result from principles already established[2]. One can lower the energy barrier, therefore, either by reducing the concentration of the external sodium or by increasing the concentration of external potassium, which in turn lessens the membrane potential.

In order to calculate the energy barriers, the membrane potential E_m must be known. Approximate values of E_m were obtained using the Graham and Gerard technique[3] on fibres of the sartorius after about 15–30 min. after the second immersion. Such potential measurements are necessarily inexact for the purpose because of changing conditions. None the less, it is to be expected that they will not be much in error and they are useful data in the present context.

In Fig. 1 the secretion results are plotted against the calculated energy barriers. The occurrence of a critical energy barrier is clearly evident from the graph. This critical energy barrier for the conditions described is of the order of 2,000 calories per equivalent of sodium. But the magnitude of the barrier may be expected to change when the conditions are much different, as mentioned below. Among other things, the graph shows that when the 104/104/10 and 120/120/10 procedures (giving no significant excretion of sodium) are changed to 104/104/30 and 120/120/30 procedures, a large excretion of sodium occurs.

Here it may be noted that when excretion occurs on reducing the external sodium concentration some fall in membrane potential occurs.

Oxygen Uptake as affected by the Critical Barrier and Sodium Excretion

A number of experiments were conducted in which the oxygen uptake was determined by the Warburg technique for the second immersions in the 104/104/10, 120/120/10 and the 120/104/10 procedures. The results are summarized in Table 1. As there was no apparent difference in oxygen uptake or sodium secretion between the 120/120/10 and the 104/104/10 procedures with respect to the secretion of sodium ions or the uptake of oxygen, these experiments were grouped together. Table 1 gives the medians as the most representative values. Fuller details will be published in a paper by Conway, Kernan and Zadunaisky. The number 63 refers to the excretion of sodium as previously established[4], the other numbers to experiments of the present series, each experiment being conducted on three sartorii, and companion muscles being in nearly all cases used for comparison with the 120/104/10 procedure.

It will be seen then from Table 1 that with this series of experiments the 120/104/10 procedure shows a marked excretion of sodium ions, in contrast to the other procedures. (Here the mean value of the excretion is somewhat higher than in the groups previously described.) At the same time, the oxygen uptake is considerably increased throughout this secretion, and the average ratio of the milli-equivalents of sodium excreted to millimoles oxygen gas taken up is 3·84 or close to 4·0. It is to be noted that the increased oxygen uptake here occurs with the same concentration of external potassium.

Further, in a series of 35 experiments carried out with the 120/104/10 procedure, there is, as usual, a rather wide distribution in the amount of sodium secreted in each single experiment. At the same time there is a very significant correlation (0·68 ± 0·1) between the sodium excreted and the oxygen uptake.

Here it may be mentioned that Keynes and Maisel[6] investigated the relation between oxygen uptake and sodium excretion from frogs' sartorii with the muscle sodium somewhat increased by immersion for 30 min. in potassium-free Ringer's fluid. The excretion was measured by isotopic exchange. These measurements at the time appeared quite satisfactory, but it is now known that due to exchange diffusion they can differ widely from the real extrusion[7,4].

Table 1. SODIUM EXCRETION, AEROBIC AND ANAEROBIC, FROM SODIUM-RICH SARTORII

The numbers in brackets refer to the number of experiments (each with three sartorii). The number 63 for the first two results listed refer to experiments from Carey, Conway and Kernan (ref. 4)

Procedure	Sodium excreted (m.equiv./kgm.)		Oxygen uptake (m.moles/kgm.)

Value of the ratio : $\frac{\text{m.equiv. sodium excreted}}{\text{extra lactic acid}}$ (taking differences between the 120/120/10 and the 120/104/30 results)			1·75	2·12

Anaerobic Secretion of Sodium Ions from Skeletal Muscle

It was shown[3,4] that the excretion of sodium in the re-immersion period of the 120/104/10 procedure could be inhibited in the average by 60 per cent. It was then obvious that, on the average, 40 per cent of the aerobic excretion of sodium could occur anaerobically. Similar results were obtained with anoxia. These conclusions were based on 74 experiments as published[4], and were much added to recently.

Such distribution shows a wide scatter, and in an appreciable fraction of the experiments there was very little inhibition, whereas in another it was almost complete.

At an early stage of such work[3], when about 13 experiments had been carried out, in which a high proportion showed very marked inhibition by cyanide, it was thought that the cyanide effect was fully inhibitory, but the accumulation of a large number of further experiments showed that the true average inhibition under our conditions was 60 per cent[3]. Recently, Frazier and Keynes[9] have stated that they were unable to find any cyanide inhibition under their conditions (which were essentially similar to ours, but differing in some points of detail).

It would seem that the concept of the critical energy barrier, and certain recent experiments based thereon, throw light on this difference. It is shown in Table 1 that decreasing the energy barrier by using 30 mM potassium ions externally instead of 10 mM completely removed all inhibition by cyanide. Thus the difference in the effect of cyanide found by the two laboratories may be referable to different metabolic states in the frog muscle used.

Explanation by the Redox Pump Theory

In this theory (refs. 2, 8, 10, 11) it is supposed that the reductant of a redox system specifically adsorbs sodium ions, and when it loses electrons to a second system these are released into solution. The energy change may be written:

$$\frac{\mathrm{d}G}{\mathrm{d}n} = F(E_2 - E_1) + [RT\ln[\mathrm{Na}^+]_i \qquad (2)$$

$F(E_2 - E_1)$ within the cell or fibre is the driving force for the excretion. The manner in which it can be considered to be utilized is as follows. If, instead of existing only in the free fibre water, the system with the adsorbed sodium ion existed in the membrane, transferring its electrons at the outermost edge to another system, with simultaneous release of sodium ions into the external fluid, the energy equation could then be written:

$$\begin{aligned}\mathrm{d}G/n &= F(E_2 - E_1) + RT\ln[\mathrm{Na}^+]_i\\ &= F(E_2 - E^1{}_1) + RT\ln[\mathrm{Na}^+]_o - E_mF \qquad (3)\end{aligned}$$

where $E^1{}_1$ represents a raised potential. From equation (3):

$$F(E_2 - E_1) - F(E_2 - E^1{}_1) = RT\ln\frac{[\mathrm{Na}]_o}{[\mathrm{Na}]_i} - E_mF \qquad (4)$$

The electrons transferred to the second redox system can either go up the respiratory chain to oxygen or, in the anaerobic state, be finally received by pyruvic or enolpyruvic acid after linking with hydrogen ions to form lactic acid. Now there is a maximum level of $RT\ln[\mathrm{Na}]_o/[\mathrm{Na}]_i - E_mF$ which is reached when $F(E_2 - E^1{}_1)$ becomes zero following increases of $[\mathrm{Na}]_o$ or E_m. If at the outset the value of $RT\ln[\mathrm{Na}]_o/[\mathrm{Na}]_i - EF$ is greater than $F(E_2 - E_1)$, no electrons can pass through the system and the critical energy-level is exceeded. The magnitude of this critical energy-level can vary with the conditions, and this is provided for in the theory.

Thus, the driving force $F(E_2 - E_1)$ can be expanded:

$$F(E_2 - E_1) = F(E_{20} - E_{10}) - \frac{RT}{F}\ln\left\{\frac{[\mathrm{Red.}]_2}{[\mathrm{Ox.}]_2} \times \frac{[\mathrm{Ox.}]_1}{[\mathrm{Red.}]_1}\right\} \qquad (5)$$

where E_{20} and E_{10} are the characteristic potentials of the systems. The expression under the log sign could be expected to vary in different metabolic states of the muscle. We may in this way interpret the fact that in the normal frog *in vivo*, or in very freshly excised muscle, the critical energy barrier must be much higher than 2,000 calories and probably at the level of 4,000 calories. The nearer the muscle to the normal condition, the greater there would seem to be the driving force. This may also explain recoveries (that is, in secretion of sodium and uptake of potassium) under certain experimental conditions when the external potassium is as low as 3·5 mM (Harris, private communication).

Thus the facts here mentioned of the critical energy barrier, of the extra oxygen with sodium excretion, and the extra lactic acid with anaerobic excretion, with approximate average ratios near 4·0 and 2·0 respectively as referred to above, are very well explained by the redox pump theory.

In the case of the anaerobic secretion, it may be noted that while there is a very significant relation between the extra lactic acid found and the sodium excreted, there is rather much variability in the ratio mentioned above. One may say that the underlying trend of the ratio is near 2·0. The variability may be explained by somewhat different states of the enzyme systems involved, even using companion muscles. That the raised concentration of external potassium is not responsible for the extra lactic acid, apart from its effect on the energy barrier and the consequent excretion of sodium, would appear from the absence of this effect when comparatively little muscle sodium was present for excretion, as when 10 mM potassium chloride was incorporated in the soaking fluid. Also, it may be added, there appeared no contractures at any stage, under the conditions.

Space does not permit of further considerations of important points of detail in this presentation, but it is hoped to deal with these matters in coming communications with Drs. Kernan and Zadunaisky and with Miss Mullaney.

LETTERS TO THE EDITORS

ASTROPHYSICS

Local Increase of Intensity of Cosmic Radiation

DURING the International Geophysical Year, no important proton event of solar origin was detected on the Earth by the different stations; but on the other hand, high-altitude balloon flights show that arrivals of low-energy protons to the polar regions were rather frequent events. These arrivals of protons are generally preceded by a solar flare associated with a radio outburst of type IV, and are accompanied by ionospheric absorption, total or partial, in the polar regions.

As these events are of considerable importance in the investigation of Earth–Sun relations, we thought it interesting to communicate some local increases of the cosmic-radiation intensity (impact region), detected by stations on the Earth, which seemed difficult to explain at the time they occurred. The correlations between these increases and the information given by other stations or observatories will perhaps make it possible to find the exact cause of these events.

Thus, on December 4, 1957, we recorded at the Paris Cosmic Ray Survey Station (geomagnetic co-ordinates: 51·2° N., 84·7°, altitude: 90 metres), by means of an unshielded telescope detecting the total component, an increase in intensity of cosmic radiation.

Particulars of the equipment are as follows: Thickness of the materials constituting the roof of the Paris Cosmic Survey Station reduced to gm./cm.^{2}: 2·5 gm./cm.^{2}. Characteristics of the unshielded telescope detecting the total compound: 3 trays of 7 counters assembled in threefold coincidence. Aperture angle: 130° × 130°. Thickness of the materials which constitute the telescope reduced to gm./cm.^{2}: 9 gm./cm.^{2}. Average counting-rate: 227 counts/min. at a pressure of 760 mm. of mercury. Characteristics of the shielded telescope detecting the hard component: 3 trays of 5 counters assembled in threefold coincidence. Aperture angle: 55° × 110°. Shielding: 10 cm. of lead, 1 cm. of steel. μ-meson detection threshold: 165 MeV. Average counting rate: 87 counts/min. at a pressure of 760 mm. of mercury.

The recording of received impulses is done by a printing clock, which marks the times for 10,000 impulses. On average we thus obtain a record covering 44 min. (or 227 counts per min.) for a barometric pressure of 760 mm. mercury.

An increase, of 18 ± 2 per cent total amplitude, the maximum of which occurred at 22 hr. 45 ± 20 min. U.T., began at 21 hr. ± 20 min. U.T. and finished at 0 hr. 15 ± 20 min. U.T. on December 5, 1957 (Fig. 1). It was not detected on the hard component. The effect was therefore preponderant on the soft component.

We inquired whether this event had been recorded by other stations. Only the station at Thule (geomagnetic co-ordinates: 88·0° N., 1·1°) showed an increase of 5 per cent between 18 hr. and 20 hr. U.T. on the nucleonic component[1] (Fig. 1). As the records of this station were only recorded *bi*-hourly, it is possible that the increase would be more prominent on a shorter recording period.

The maximum time between the onset of these two increases of cosmic-ray intensity should be 3 hr. ± 20 min.

This event took place during a period of relatively quiet solar activity. For the whole day of December 4, 1957, only one important radio outburst was detected at Ottawa[2] on 2,800 Mc./sec., at 16 hr. 57·5 min. U.T., coinciding with a flare of importance 1 observed at Huncayo (16 hr. 56 min.–17 hr. 04 min.; max. 16 hr. 58 min. U.T.;—20·5–18° W.)[3].

The delay between this solar event and the increase recorded at the station at Thule should be 2 ± 1 hr.: a delay analogous in rough approximation to those corresponding to the arrival of protons of solar origin[4].

It must be noted that the heliographic longitude of the flare (18° W.) corresponds to the part of the Sun where protons emitted during a flare have a great probability of being observed in the vicinity of the Earth[5]. On the other hand, the increase at Thule took place during a period of small magnetic activity ($Kp = 1^-$ during 18–21 hr. U.T.), whereas the Paris event took place during a period when the magnetic activity began to increase ($Kp = 2^+$ during 21–24 hr. U.T. and 4° during 0–3 hr. U.T.)[6] (see Fig. 1). This may explain the delay noticed between the increases observed on the Thule and Paris records.

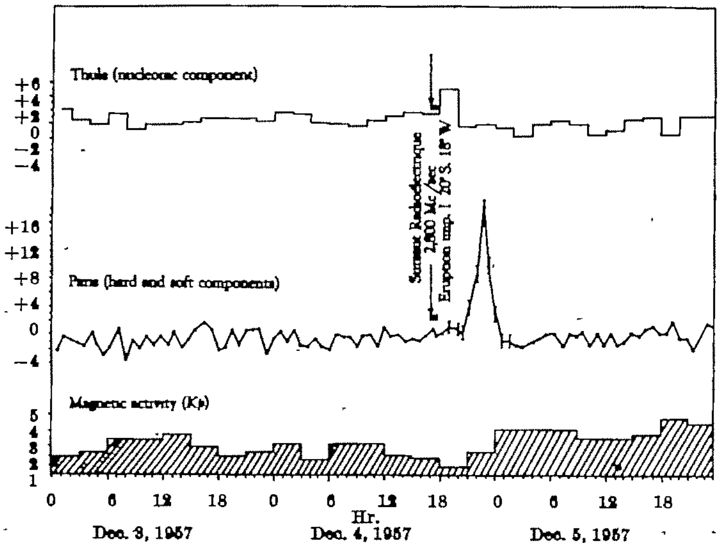

Fig. 1

Indeed, cosmic-ray particles with an energy less than that for geomagnetic cut-off in the latitude of Paris, which are generally forbidden, could in consequence of the increased magnetic activity penetrate by impact at this latitude. An analogous event was recorded at the Paris station on January 21, 1957 (ref. 7).

All these different events and the way in which they occurred suggest an arrival of protons of solar origin; but their small magnitude makes it necessary to have further experimental observations for a definite conclusion.

RADIOPHYSICS

A Highly Directive Rotating Array for 16 Mc./s.

THE typical rotating back-scatter sounder[1,2] uses a horizontal 3 or 4 element Yagi for both transmission and reception. The main-lobe width for such aerials is commonly about 60° between half power points, and when the aerial is used in conjunction with a 'transmit–receive' switch the effective lobe width reduces to about 40°. This means that echoes will tend to become 'smeared out' in azimuth to a greater or lesser degree depending on the received signal strength.

One of the investigations being undertaken at Brisbane is concerned with the detection and analysis of echoes from field aligned ionization in the *F* region of the ionosphere[3], and for this purpose it is desirable to achieve some finer degree of discrimination of the azimuthal extent of echoing regions than is possible with the simple Yagi system. Considerable thought has been given to the design of a large low-cost rotatable array of aerials, and some degree of compromise proved to be necessary.

The system chosen consists of 4 three-element Yagis separated by 1·1 wave-lengths, mounted on a truss 228 ft. long pivoted at its centre, and supported by four bogies with normal truck wheels and balloon tyres running on concrete tracks (Fig. 1).

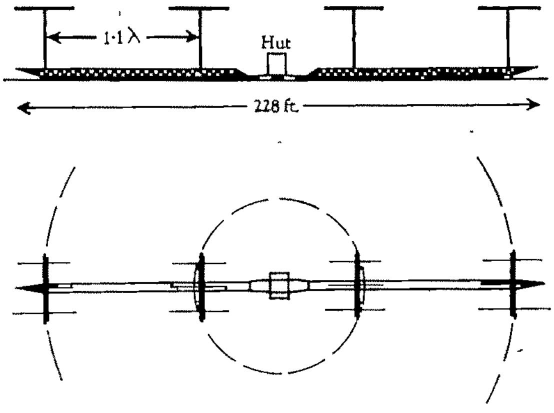

Fig. 1. Elevation and plan views of rotating array

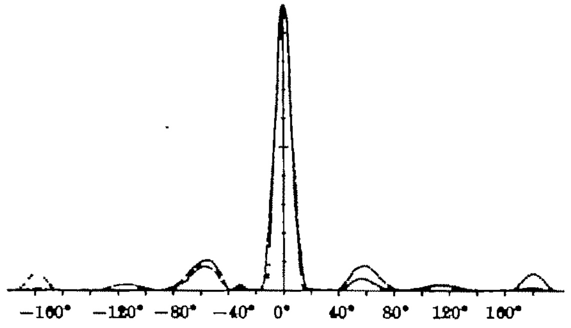

Fig. 2. Radiated power versus array orientation (in the horizontal plane). – – –, Computed power; . . . ., measured power

Each Yagi is constructed entirely of aluminium and mounted at the top of a guyed aluminium mast 30 ft. above ground-level. (This height gives maximum signal at an elevation angle of about 25°, a value suitable for the experiments in hand.) All the Yagis are fed in the same phase, and the relative currents are chosen to reduce the intensity of side lobes near the main beam. The computed aerial gain is 150.

A comparison of the computed and measured azimuthal radiation pattern of the aerial array is given in Fig. 2. The two major lobes at ± 55° are reduced from an amplitude equal to that of the central beam only by virtue of the reduced radiation from each individual Yagi in this direction. The high front-to-back ratio of the system is likewise entirely produced by the Yagis. The small degree of asymmetry shown in the measured pattern is not of any

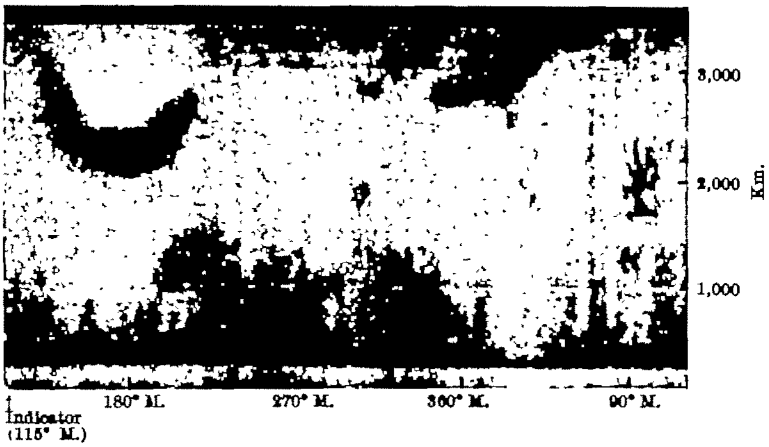

Fig. 3. Range-azimuth record using 16 Mc./s. array at Brisbane 0020, May 7. 1960. The U-shaped trace centred on 180° M. is typical of the aspect-sensitive reflexions obtained

major importance when the array is used both for transmission and reception. Under such conditions the effective beam-width is 8° (to half-power points), and the lobe at − 55° is 19 decibels down with respect to the main beam, thus giving a considerable increase in azimuthal resolution over the use of a single Yagi. The back lobe is 24 decibels down with respect to the forward beam.

The system is rotated by two 1 horse-power electric motors hydraulically coupled and geared down to drive one of the wheels on each outer bogie. Normal speed of rotation is one revolution in 3 min.

Fig. 3 shows an example of a range-azimuth display obtained using the array, which illustrates the particular advantage of the narrow beam for the purpose of identifying aspect-sensitive reflexions.

Radar Determination of the Scattering Properties of the Moon

INFORMATION about the scattering properties of the Moon's surface has been deduced by Evans[1] from the rapid fading of lunar radio echoes. His results were obtained by picturing the surface as an assembly of randomly spaced scatterers. Such a concept, however, does not take into consideration the distribution in depth of the scattering elements. An approach which does so is that adopted by Feinstein[2], who used Huygens's principle to study the general problem of reflexion from a plane surface having random irregularities that are a function both of the space co-ordinates and of time. With minor modifications to take into account the curvature of the reflecting surface, Feinstein's results may be applied to lunar radio echoes.

Consider first the lunar surface to be corrugated in one dimension only, so that its height h above a mean level can be represented by the random variable $h(x,t)$, where x is distance measured along the surface from its intersection with the line connecting the centres of the Earth and the Moon. If the resultant surface velocity due to the lunar librations is v, and if the co-ordinate plane is determined by this vector and the line of centres, the function h will have the form $h(x - vt)$.

Now assume that h is normally distributed and that the joint distribution of the h's at any two points is bivariate normal. The space correlation function of the signal envelope observed by spaced receivers on the Earth's surface when the Moon is directly overhead can then be shown to be:

$$C(s) = \exp\{-a[1 - \rho(sR/2D)]\} \qquad (1)$$

where s is separation between receivers, a is $4k^2\overline{h^2}$, k is $2\pi/\lambda$, where λ is the radar wave-length, $\overline{h^2}$ is variance of the distribution of h, ρ is normalized space correlation function of the lunar surface, R is radius of the Moon, D is Earth–Moon distance.

By fitting experimental data to (1), it is possible to determine both the lunar space correlation function ρ and the constant a, since $C(s)$ approaches $\exp(-a)$ asymptotically. It is important to note, however, the occurrence of an approximately 500-fold change in the scale of this function that results from the reflexion of the incident wave-front at the curved lunar surface. Space diversity tests carried out by the U.S. Army Signal Research and Development Laboratory over its circuit from Belmar, N.J., to the University of Illinois, at Urbana, Ill., have verified this expansion in scale.

The autocorrelation function of the received signal envelope at one location on the Earth's surface is given by:

$$P(\tau) = \exp\{-a[1 - \psi(\tau)]\} \qquad (2)$$

where $\psi(\tau)$ is the autocorrelation function that would be observed at any point on the mean lunar surface that is fixed relative to the co-ordinate system postulated. Because of the relation between x and t, it is immaterial whether we determine $P(\tau)$ or $C(s)$ experimentally, since both contain the same information. Only $C(s)$, however, is expanded by the factor $2D/R$.

The one-dimensional results for the correlation functions are directly applicable to the two-dimensional case, if the variance of h is independent of direction. For the determination of the distribution of angular power, however, the lunar surface must be treated as two-dimensional, and, in addition, the form of the function ρ must be specified. Feinstein[2] has derived the angular distribution for the case where:

$$\rho = \exp(-d^2/l^2) \qquad (3)$$

where d is distance measured in any direction along the lunar surface and l (or more commonly $l/\sqrt{2}$) is called the structure size. Because surface irregularities much smaller than λ will not appear in the reflected wave-front, the smallest value of l determinable from radar observations will be of the order of magnitude of λ. If Feinstein's results are again modified to fit the lunar problem, the angular power distribution is found to be:

$$p(r) = (\exp - a)\left[\cos(kr^2/R) + \sum_{n=1}^{\infty} \frac{a^n}{n.n!} \exp(-r^2k^2l^2/nR^2)\right] \qquad (4)$$

In order to determine $p(r)$ completely, we must first assume that $\rho(d)$ has the form given in (3) and obtain numerical values of a and l by fitting observational data to (1) or (2). These values of a and l are then substituted into (4).

GEOPHYSICS

Anomalous Leads from a Selected Geological Environment in West-Central New Mexico

A DETAILED study of lead isotopes has been undertaken in order to evaluate variations in the isotopic composition of lead with respect to the geological environment of the sample area. Support for the project is being provided by the New Mexico Bureau of Mines and Mineral Resources division of the New Mexico Institute of Mining and Technology and by the Geophysics Laboratory of the University of Toronto.

A field area was desired in which the number of geological variables would be at a minimum. An area of approximately 5,000 square miles in west-central New Mexico was found to satisfy this requirement. Barite-fluorite-galena deposits are scattered throughout the field area[1,2]. These deposits have identical mineralogy, very similar geological settings with respect to host rock type, and a common depth-temperature type of mineral deposition. Within the field area, the Hansonburg mining district was selected for detailed studies of single galena crystals and for determination of local isotopic detail across parallel north–south mineralized fractures. The other samples have been taken from localities scattered across the field area in order to investigate the possibility of widespread isotopic variations. The location of sample number 1054 is unique in that it is located near deep-seated acid intrusives, but here too the mineralization is very similar to that of the other sample locations[3].

Galena (PbS) was the mineral collected from each site chosen for this preliminary study. Fresh, unweathered specimens were utilized, and wherever possible the entire sample was taken from a single galena crystal. When the samples contained only fine-grained, disseminated galena, the sample was crushed and pulverized to minus 20 mesh, screened, and a heavy mineral concentrate prepared by panning. Fresh galena was then hand picked from the heavy mineral concentrate under a microscope.

Following the sample preparation at the New Mexico Bureau of Mines, the samples were sent to Toronto for analysis. The hand-picked samples of galena were dissolved in hydrochloric acid, and the lead ions precipitated as lead iodide. A Grignard reaction of lead iodide and methylmagnesium bromide at room temperature was used to produce lead tetramethyl. The lead tetramethyl was mass analysed in the Nier-type 180-deg. mass spectrometer operated by the Geophysics Laboratory of the University of Toronto. The precision of the various analyses is shown in Table 1.

Table 1. PRECISION OF ANALYSES

Lead isotope	Sample variation range	Average sample variation
204	$S = \pm 0\ 001$ to $\pm 0\ 011$	$S = \pm 0\ 005$
206	$S = \pm 0\ 02$ to $\pm 0\ 08$	$S = \pm 0\ 04$
207	$S = \pm 0\ 02$ to $\pm 0\ 06$	$S = \pm 0{,}03$
208	$S = \pm 0\ 03$ to $\pm 0\ 09$	$S = \pm 0\ 05$

$S = \pm \left[\frac{\Sigma (s - \bar{s})^2}{n - 1}\right]^{1/2}$. This is the precision of an individual mass scan and is not the error of the average values reported in Table 2.

A large crystal of galena from the wall of an open fracture zone in the Hansonburg district was selected for detailed study. The galena crystal, illustrated in Fig. 2, had the form of a cube cut in half along a diagonal plane. The diagonal surface of the crystal was attached to a large breccia fragment of silicified limestone. The crystal was sampled by cutting it into small cubes with a diamond saw. A corner (sample 111) and two samples along a diagonal (samples 222 and 333) were analysed. The positions of these samples are indicated in Fig. 2. The corner sample was found to be distinctly different from the internal samples. The compositions of the crystal samples are listed in Table 2 under sample number 1049.

Samples of galena were collected along east–west lines across the north–south mineralized fractures in the Hansonburg mining district. Small, consistent

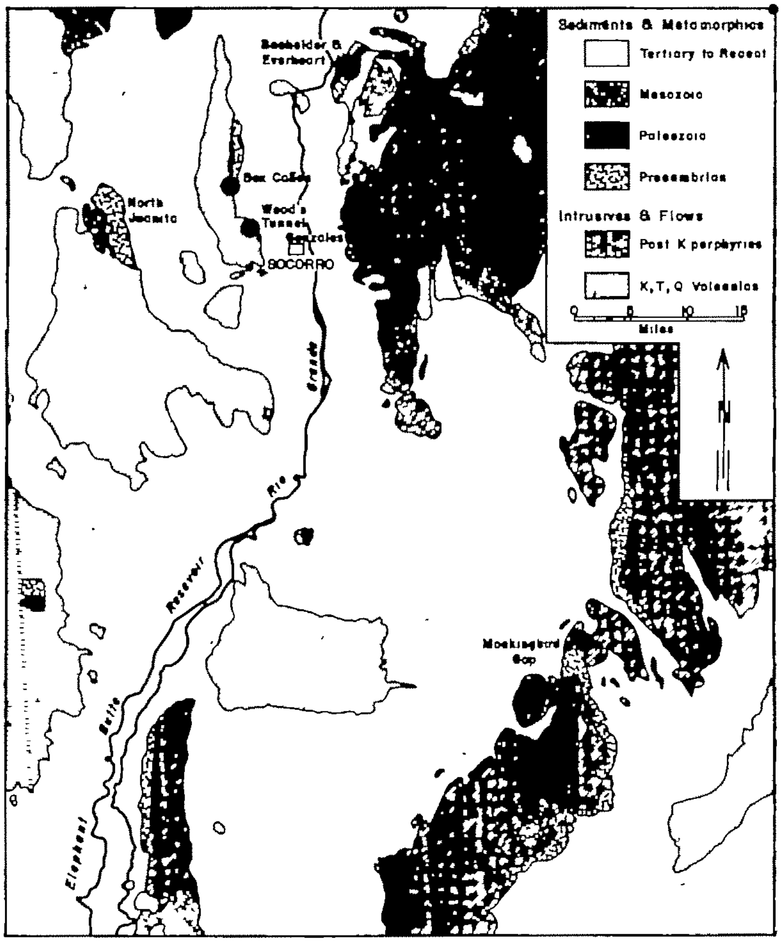

Fig. 1. Map of field area showing location of samples

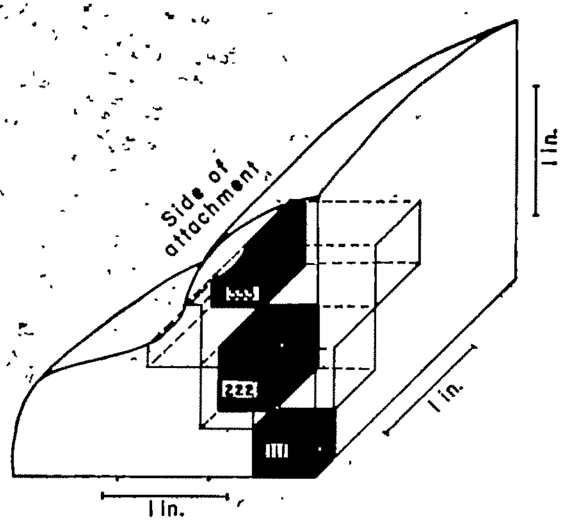

Fig. 2. Single crystal with sample positions shown

variations in isotopic composition were found from west to east. Radiogenic lead was found to increase to the east. Samples 1,040, 1,046 and 1,047, taken from west to east, illustrate this. The sample spacing is 200 ft. between samples 1,040 and 1,046, and 100 ft. between samples 1,046 and 1,047. No north–south trends were noted in the Hansonburg mining district.

Regionally, the geological map of New Mexico[4] suggests a northwest-trending basement structure underlying samples 1,054, 1,059 and 1,065. These three samples have had distinctly less radiogenic lead added to them during their history of emplacement than the other samples taken in the field area. Such isotopic variations suggest that basement structure may be reflected by the isotopic composition of the lead present in the overlying mineral deposits.

When all of the samples are plotted as lead-207/lead-204 versus lead-206/lead-204, they fall in a straight line. The slope of this line, as determined by the least squares method, is 0·0938. Applying the method of Farquhar and Russell[5], the maximum age for the source of the radiogenic lead additions is calculated as 1,530 million years. This figure agrees fairly well with the age of 1,300–1,450 million years given by Tilton and Davis[6] for the basement rocks of the south-western United States.

Table 2. Presentation of Data

Mine name or sample location	Sample number	Percentage			
		Pb-204	Pb-206	Pb-207	Pb-208
Hansonburg district Sunshine-Blanchard	1,040	1·252	27·86	20·06	50·82
	1,046	1·247	27·97	20·09	50·68

Gonzales	1,056	1·242	27·83	19·96	50·96
Box Cañon	1,057	1·290	26·66	20·47	51·58
Bacheldor-Everheart	1,058	1·263	26·77	20·10	51·87
Salinas Peak	1,060	1·208	28·47	19·46	50·86
	1,061	1·212	28·28	19·48	50·92
	1,062	1·203	28·49	19·43	50·88
	1,063	1·203	28·64	19·37	50·80
	1,064	1·205	28·51	19·45	50·83

The preliminary work reported herein indicates that continued research is warranted within the limited field area selected. The lines of isotopic research being continued by us are: (1) Delineation of basement structure. (2) Single-crystal detail to obtain relative ages for isotopic variations within local areas. (3) Delineation of local isotopic trends, such as the east–west trend found in the Hansonburg mining district.

PHYSICS

A Method for the Routine Measurement of Particle Shape Factors in the Sieve Range

SIZE distribution cannot alone describe a particle population, and for some purposes it becomes necessary to measure the particle shape within closely sized ranges. Some instances of the use of shape factors are in estimating approximate surface areas, calculating the number of particles in a size range and investigating the variation of particle shape with size. Since these applications are not confined to one field or industry, interest in shape factor is widespread.

If k and f are the volume and the surface shape factors respectively, then by definition:

$$V = kd^3$$

and

$$S = fd^2$$

where V is particle volume, S is surface area and d is some measure of the particle diameter. It is usual to use the statistical diameter[1–3], but for the present purpose the geometrical mean between the limiting and retaining screen apertures on the British Standard $\sqrt[4]{2}$ scale[4] is convenient. Heywood[5] has given relationships between statistical and sieve aperture diameters for various particle shapes. Clearly, these definitions must be interpreted statistically; V and S represent the mean of a large number of measurements. Consequently, although particle shape factors as defined here are simple in conception, their experimental determination is laborious since it may be necessary to sample, count and weigh several thousand closely sized particles. However, particularly careful work of this nature has been reported for coal particles[4] but generally there is not much published work on this topic.

Routine shape factor measurements for particles smaller than about 36 British Standard mesh (500μ) will be undertaken reluctantly with such slow and tedious counting methods. The alternative automatic scanning procedures, though speeding the process, require expensive equipment. With this in mind a simple method for counting and weighing large numbers of closely sized particles was developed.

The original procedure[7,8] used a sieve, which was the limiting screen for the closely sized particles under investigation, carrying on its underside a weighed strip of 'Cellotape' of known area. Consequently, the number of covered apertures could be calculated. This will be referred to in the following as the 'working surface'.

The particles of known density were dusted over the working surface and generally one particle per aperture was retained by the adhesive film on the 'Cellotape'. However, a few exceptions were noted. If a wide range of shapes occurred within a size fraction it was found that the number of particles per aperture varied from none to two or three. While these frequently averaged one per aperture, as a refinement a few sample rows were counted by scanning with a travelling microscope. Since the particles were arranged in a rectangular matrix this proved a simple operation. With the larger particle sizes a simple precaution was necessary; because the 'Cellotape' must cover an integral number of apertures it was therefore preferable to measure the effective area of the working surface after dusting with particles. Carefully removing the 'Cellotape' with its adhering particles and re-weighing enabled the average weight and volume of a single particle to be calculated. Thus, k may then be determined directly, and f may be calculated from specific surface area data.

While the application of a mesh in this manner for particle counting was found to be a most useful innovation (it has since been discovered that the idea of counting by using a specially moulded plate holding one particle per recess is sometimes employed when bottling pharmaceutical products such as aspirin), the two main steps: (*a*) measuring the area of the 'Cellotape' for each determination; (*b*) peeling the 'Cellotape' away from the sieve for re-weighing, were inconvenient and the original method has been improved.

Disadvantage (*b*) is avoided by using rimmed British Standard mesh disks of about 7-cm. diameter. These weigh about 20 gm. and consequently the entire disk and 'Cellotape' with the adhering particles *in situ* can be weighed on an analytical balance.

Disadvantage (*a*) is not as easy to overcome as (*b*) but fortunately it is not as serious. However, if a mesh were available containing a known standard number of apertures then the entire surface could be covered with 'Cellotape' and area determination would be unnecessary. Utilizing this idea it was found that mesh rectangles were easily cut to give a working surface containing a standard number of apertures. However, these meshes possessed little mechanical strength, becoming both easily distorted and frayed at the edges. Sealing the edges to a depth of several aperture diameters with a plastic material, while still retaining a rectangular working surface, completely obviated these disadvantages.

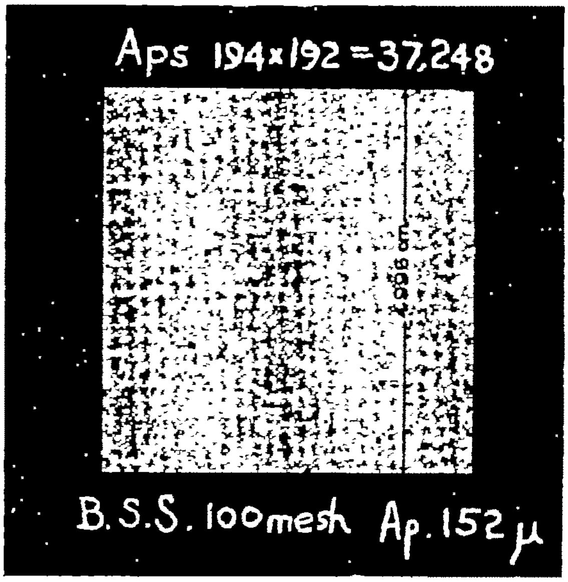

Fig. 1. Standard count mesh · 100 British Standard (152-μ aperture) containing 37,248 apertures

The technique of making these meshes is to use 'Cellotape' to avoid sealing the working surface when the plastic is applied to the edge and is given in the Appendix. Fig. 1 illustrates a standard aperture count mesh made from a 7·5-cm. square of 100 British Standard mesh (152-μ aperture, 102-μ wire diameter). Its edges were sealed to a depth of about 40 apertures (~ 1 cm.) and the working surface contains 37,248 apertures. Fig. 2 shows a magnified section near a corner of this mesh after dusting with coal particles sized between 100 and 120 British Standard mesh (152–124μ). This incidentally illustrates how sieves tend to select some coal particles along a diagonal and indicates that the ratio between the statistical diameter and the mean sieve aperture should be $\sim \sqrt{2}$. Values reported by Needham and Hill[9] support this.

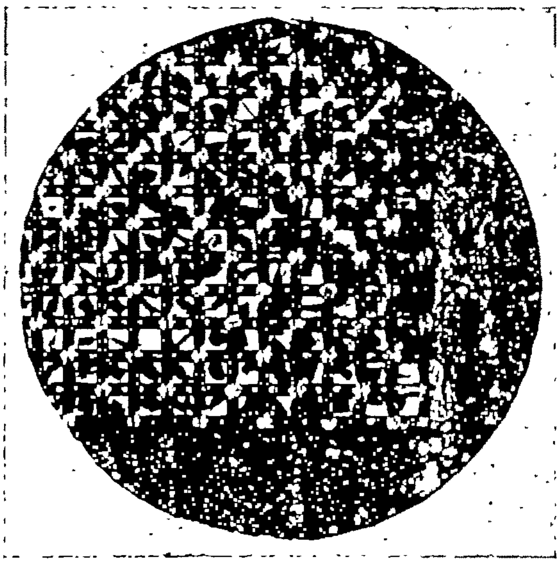

Fig. 2. Corner of mesh in Fig. 1 after dusting with 100–120 British Standard mesh coal particles (scale: aperture 152μ, wire diameter 102μ). Photograph taken by transmitted and reflected light. The highlights caused by reflexion of light from the wires have been reduced in intensity

This technique becomes difficult with meshes finer than about 100 British Standard. However, having sealed the edges, even though the working surface may not be rectangular, and consequently estimating the number of apertures becomes laborious; once the number is counted the operation need never be repeated. A photographic enlargement of the mesh is useful here.

For counting the finer particles, electrolytically deposited grids have been used. These have excellent mechanical strength and can be cut easily to produce a standard rectangular working surface. Sealing the edges is not necessary as it is with meshes and this is a decided advantage. However, preliminary results indicate that they are slightly inferior to woven mesh, for often two particles occupied one aperture. The grid is thinner than the correspondingly sized mesh, and its wires are rough and rectangular in section as against smooth and circular; observation indicates that these factors may have some influence on the adverse effects noted. Nevertheless, a technique for using these grids could probably be developed.

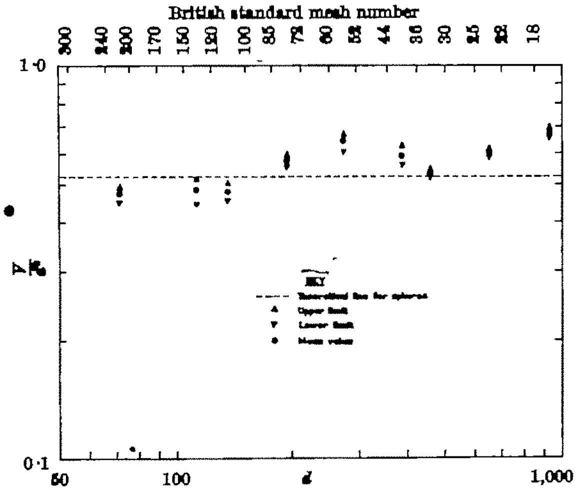

Fig. 3. Relationship between shape factor and mean particle size: coal sample

It is suggested that suitable fine meshes could be specially woven for this purpose. These would contain a standard number of apertures to British Standard or any other specification surrounded by a closely woven edging which would serve both to suitably terminate the working surface and to strengthen the mesh. A large number of these standard aperture count meshes could be woven simultaneously as one piece of cloth, the 'pattern' being (say) 5-cm. squares of working surface separated by 1-cm. wide stripes of close weave. These could be cut and suitably mounted. It should be noted that for 100 British Standard mesh material a 5-cm. square of working surface would contain about 40,000 apertures.

Preliminary results were reported earlier[7,8] where with a particular coal sample an average of $k = 0{\cdot}54$ was obtained. Interesting confirmation of this value based on Heywood's work has since been communicated (Bramley, J., private communication, reproduced in ref. 8).

Some recent measurements on coal samples are illustrated in Fig. 3, which demonstrates a variation in k with particle size. The method of plotting is clearly more revealing to changes in k than the usual logarithmic plot of V against d. Also, if a differently defined measure of particle size is introduced as a ratio with d then a plot by dimensionless groups follows; this could be useful in correlating shape factor data.

This work is part of a project concerned with the moisture retention properties of fine coal.

I wish to thank Prof. J. T. Whetton and my colleagues in this Department for interest, and especially Mr. D. Howitt, who carried out the experimental work.

Appendix. A Method for making Standard Aperture Count Meshes

(1) Commence with a suitably sized mesh rectangle which has been cleaned in a grease solvent. A 7·5-cm. square was used here.

(2) Stick a strip of opaque 'Cellotape' on to the mesh so that the outer edge of the tape lies along and covers a wire situated about 1 cm. from the edge of the mesh. Repeat on the reverse side of the mesh for the same wire.

(3) Repeat the operation for the opposite edge of the mesh.

(4) Apply a layer of plastic material to both sides of one uncovered edge and quickly spread evenly on both sides with a spatula. Treat the opposite edge in the same way. An epoxy resin and a proprietary brand of plastic solder have both been used successfully.

(5) When the plastic is dry, but still soft, peel the 'Cellotape' away and a straight clean edge should result. To assist this it is sometimes advantageous to score the plastic gently with a sharp knife.

(6) When the plastic has hardened treat the remaining edges in the same way.

D. HOWITT

Gallium Arsenide as a Semi-insulator

SOME semiconductors have comparatively low resistivity, and this is due to their containing electrically active impurities with energy-levels near a band edge. Others have very high resistivity and this is due to their containing a predominance of impurities with levels far from the band edges, that is, far compared with the thermal energy kT. These latter materials are often referred to as insulators, but since they can carry electronic currents we prefer to introduce the term 'semi-insulator' to describe them. A material such as cadmium sulphide, which by suitable choice of impurity content can be made a semiconductor or a semi-insulator, is of particular interest and much work has been done on cadmium sulphide in the past few years. Gallium arsenide is another substance with the same property, but has the advantage that both n- and p-type material may be readily prepared.

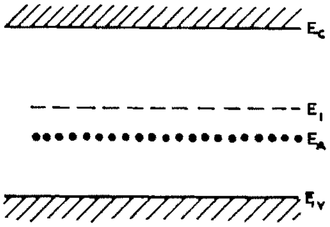

Fig. 1. Energy-levels of the model to be considered

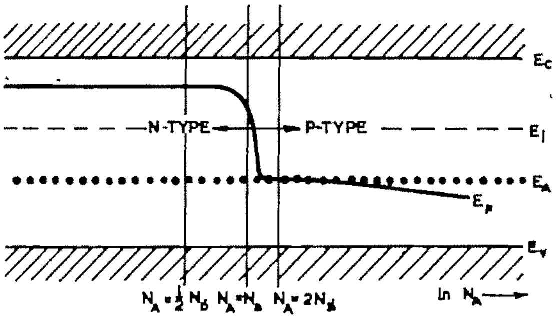

Fig. 2. Fermi-level as a function of acceptor concentration for fixed donor concentration (schematic)

As normally prepared in this laboratory undoped gallium arsenide is *n*-type with about 10^{16} electrons/cm.^{3}, which come from a residual impurity acting as a shallow donor. Under conditions in which oxygen is present during the preparation high-resistivity material is obtained. The most reasonable hypothesis is that oxygen gives rise to a deep acceptor-level which compensates the donors. It is therefore of interest to consider the behaviour of a system with a given concentration of donors N_D and a variable number of deep acceptors with concentration N_A. My experiments suggest that the acceptor-level at E_A lies below the intrinsic Fermi-level E_i, as shown in Fig. 1. The Fermi-level varies with N_A in the manner shown schematically in Fig. 2. It will be of advantage to introduce a quantity:

$$\chi \equiv \frac{N_A}{N_D}$$

which I shall call the 'degree of compensation'. Four regions of interest may be distinguished:

(1) $N_A \ll N_D$, $\chi \ll 1$. The concentration of electrons in the conduction band n is, to a good approximation, equal to N_D and the material is low resistivity *n*-type.

(2) $N_A \simeq N_D$, $\chi \simeq 1$. The Fermi-level drops from a position near the conduction band to one near the acceptor-levels, this change occurring over a very small change of N_A. For example, if N_A is 0·9 N_D then n is 0·1 N_D and the material is still of fairly low resistivity, the Fermi-level having dropped from its position in region 1 by only kT ln10 (about 0·06 eV. at room temperature), while if N_A is 1·1 N_D then the Fermi-level has dropped to a position only kT ln10 above the acceptor-level, and n will decrease by many orders of magnitude. In the present model which has E_A below E_i the material will change from high resistivity *n*-type to high resistivity *p*-type in this region. When N_A is greater than but not much greater than N_D the electron concentration is given by:

$$n \simeq \frac{1}{\chi - 1} \, . \, N_c \, . \, \exp \frac{E_A - E_c}{kT} \qquad (1)$$

that is, it is determined by the degree of compensation and the acceptor energy-level only. From the absolute magnitude of n and its variation with temperature both χ and $E_c - E_A$ may be determined.

(3) $N_A > N_D$, $\chi > 1$. As soon as N_A becomes appreciably greater than N_D the Fermi-level becomes locked near the acceptor-level and the material is high resistivity *p*-type. In this region the hole concentration is given by:

$$p \simeq (\chi - 1) \, . \, N_v \, . \, \exp \frac{E_v - E_A}{kT} \qquad (2)$$

It should be noted that the range of validity of equation 2 is the same as that of equation 1, for both hold when the position of the Fermi-level is determined by N_A and N_D alone, p and n both being negligible.

(4) $N_A \gg N_D$, $\chi \gg 1$. The position of the Fermi-level is now determined by the distribution of electrons between the valence band and the impurity-level. As N_A increases the hole concentration increases, but since E_A is far from E_v then p cannot be large and the material is still high resistivity *p*-type. In this region:

$$p \simeq (N_v N_A)^{\frac{1}{2}} \exp \frac{E_v - E_A}{2kT} \qquad (3)$$

By considering Fig. 2 it is easy to see what modifications to this behaviour are introduced if E_A lies above E_i. The general shape of the curve of E_F against N_A is unchanged but now the point of intersection of E_F with E_i is moved to the right, that is, the change from high resistivity *n*-type to high resistivity *p*-type occurs at a much higher acceptor concentration, and in practice this may not be attainable.

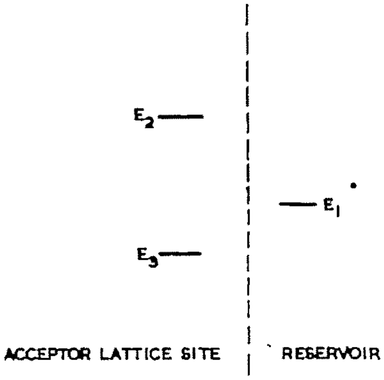

Fig. 3. The energy scheme for the formation of an acceptor during auto-compensation

Experimentally it is found that in semi-insulating gallium arsenide E_A does lie below E_i. The existence of *n*-type high resistivity material requires that $\chi \sim 1$ and we find from the experiments, using equation 1, that $\chi - 1$ is as little as 10^{-4}. Clearly it is unlikely to happen in a large number of specimens that N_A should approach N_D so closely just by chance, and some mechanism of automatic compensation must be operative. A rather general model for this is illustrated in Fig. 3. Again we regard N_D as a fixed given quantity. There is a reservoir of lattice defects (in which term I shall include impurities) which are in an electrically inactive state at energy E_1. These can go over to lattice sites at which they behave as acceptors, with energy E_2. If in this site they accept an electron the energy of the crystal decreases by an amount $E_c - E_A$, and this state has energy E_3. One then has a problem in statistical thermodynamics in which defects are distributed over levels E_1, E_2, E_3 and electrons over levels

E_2, E_1, E_3, the two systems being coupled by the fact that the level E_2 has an electron associated with it. To investigate this model in detail requires a more exact specification of the states; but it is immediately obvious that if the energy differences $E_2 - E_1$ and $E_1 - E_3$ are both large compared with kT and the entropy difference between the states is not too great then almost exact compensation will occur as long as the reservoir contains sufficient defects. In other words, it is energetically advantageous for defects to become acceptors so long as there is an electron for them to accept, but not otherwise.

An alternative possibility is that acceptors and donors form associated pairs[1], but this mechanism should lead to an increase in electron mobility, contrary to observation. Also the calculated degree of pairing is insufficient to account for the exactness of compensation found.

In the case of semi-insulating gallium arsenide it seems probable that oxygen is dissolved in the lattice in two different sites, being electrically active in one site (as an acceptor) and inactive in the other (as the reservoir). In the case of cadmium sulphide and similar compounds, the work of Kröger and Vink[2] shows clearly that the deep levels are associated with crystal defects arising from non-stoichiometry, and the reservoir of such defects is obviously the ambient atmosphere. In cadmium sulphide one can vary χ by annealing crystals at various temperatures and in various atmospheres, and similarly in gallium arsenide one should be able to vary χ by suitable heat treatment.

My model suggests that semi-insulators of the type I have described, that is, those in which a shallow donor is auto-compensated by a deep acceptor, should exhibit pronounced hole trapping effects but little electron trapping. This has a number of practical implications. For example, the high photoconductivity of these materials is readily explained. Also the existence of large space-change currents in certain crystals of cadmium sulphide[3] but not in others may be explained by variations in χ between the crystals. One might predict that semi-insulating gallium arsenide suitably heat-treated might also show such currents.

The ideas expressed here were developed while attempting to account for the experimental results of Dr. G. T. Wright on cadmium sulphide and of Dr. C. Hilsum and his colleagues on gallium arsenide. I wish to thank them both for extensive discussion of the problems involved.

Gallium Arsenide for γ-Ray Spectroscopy

CRYSTAL conduction counters offer an improvement in energy resolution over ionization chambers or scintillation counters for spectroscopy of nuclear particles. Semiconductor counters which employ a *p–n* junction are useful only for heavy charged particles of moderate energy. For energetic charged particles or γ-rays with ranges exceeding 1 mm. of silicon a crystal with efficient charge collection throughout its bulk is required. Most crystals of sufficiently high resistivity contain so many electron traps that collection of the ionization current is inefficient, and only diamond has previously been found to count single γ-ray events. The usefulness of diamond as a crystal counter is restricted.

We have found that the semiconductor gallium arsenide with resistivity at room temperature exceeding 10^8 ohm-cm. is an efficient particle counter. When a bar of this material is bombarded with γ-radiation from cobalt-60, pulses of charge are readily observed. The time for the pulse-rise is about 5 μsec., and pulses of 0·5 mV. across a megohm load are seen with an applied field of 200 V./cm. This effect occurs in both *n*-type and *p*-type gallium arsenide of high resistivity. The samples used in these experiments were of dimensions 1 cm. × 0 2 cm. × 0·1 cm., but there appears to be no reason why larger crystals should not be made. We are examining the spectrum of the pulse-height and resolution of energy, and our results will be reported elsewhere.

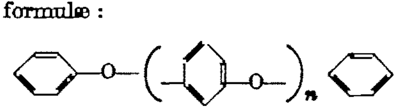
ENGINEERING

Pump Fluids for Higher Vacuums

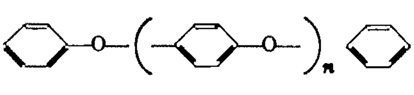
IN the decade after Burch introduced petroleum oils[1] as working fluids for the Langmuir condensation pump, the silicones, octyl alcohol esters and petroleum pump fluids converged to a low-pressure optimum at about 10^{-7} mm. mercury, which the succeeding 20 years has lowered, perhaps, to 5×10^{-8} in an untrapped three-stage glass pump when measured at an ambient temperature of 25° C.

Recently, particle accelerators and the conquest of space have made demands for pressures ten or a hundred times lower, to be induced in relatively enormous containers, and it has been necessary to augment the pumps with traps filled with liquid nitrogen or helium, together with means for periodic baking out. The proliferation of apparatus occasioned by these and other alternatives is becoming far too cumbersome and expensive.

In April 1959, learning of their use as high-temperature lubricants, I began examination of a class of phenoxy benzenes and polyphenyl ethers[2] of the general formulæ:



(1)



(2)

which may restore simplicity to the vapour pump. Not only can some of the compounds give pressures in the 10^{-8}–10^{-10} range untrapped, but also their tendency to wander through vacuum labyrinths is reduced many hundredfold over previously used fluids. Thus a Bayard–Alpert ionization gauge[3] attached to a three-stage glass air-cooled pump (type 25*W*, Consolidated Vacuum Corp.) by a tube 2 cm. in diameter with two right-angle bends showed no clouding of the glass beyond the first bend in two weeks at an ambient temperature of 30° C. The filament, energized after 54 hr. inactivity, indicated an immediate pressure of 8×10^{-8}—the initial gas burst—and 1×10^{-9} 13 min. later, without resort to degassing or baking. The lowest indicated pressure with the filling:

m-bis(*m*-phenoxyphenoxy)-benzene (3)

was $4 \cdot 5 \times 10^{-10}$ mm. mercury, again untrapped. This is equivalent to an altitude above the Earth of 400–800 km.[4], according to latitude, and a mean free path of 10–100 km., depending on the composition of the residual gas.

Table 1

Name of pump fluid	Temperature in pump boiler (approximately)	Vapour pressure (25° C., mm. mercury) (extrapolated)	Lowest pressure (mm. mercury) yet recorded in untrapped pumps, 25° C., ambient	
			1-Stage*	3-Stage†
2-Ethyl hexyl sebacate	190° C.	2×10^{-8}	1×10^{-6}	8×10^{-8}
bis (*m*-Phenoxyphenyl) ether	195° C.	10^{-9}		
m-bis(*m*-Phenoxyphenoxy)-benzene	250° C.	10^{-11}	5×10^{-9}	5×10^{-10}
bis-m(*m*-Phenoxyphenoxy)-phenyl ether	280° C.	10^{-12}	5×10^{-8}	
Mixed meta- and para-5-ring ethers	250° C.	$<10^{-12}$	5×10^{-7}	$1 \cdot 1 \times 10^{-9}$

* This experiment, tested in vertical glass pump, with *Vg*. 1*a* gauge tube.

† This experiment, tested in 3-stage glass fractionating pump, with Bayard-Alpert *G.I.C.* 110 tube.

The results of some early comparative tests are shown in Table 1, while the gas bursts at ultimate vacuum are recorded at an ambient temperature of 30° C. in Fig. 1. The single-stage pump was fitted with a *Vg*. 1*a* ionization gauge tube through two right-angle turns; and the three-stage pump with a Bayard–Alpert gauge *G.I.C.* 110. In each case, the gauge had been de-energized for 16 hr. after reaching a low-pressure plateau, and it is the response immediately after re-energizing the filament that is shown in Fig. 1. Other compounds, tested only in the single-stage glass pump, for lack of material, showed considerable promise, for example:

bis(*m*-(phenoxyphenoxy)-phenyl) ether (4)

which on one occasion reached an unreadable value with the *Vg*. 1*a* ionization tube. A 5-ring meta-para-isomer gave a very high vacuum in the three-stage pump, 1×10^{-9} or better. Since the vapour pressures at room temperature of the 5-ring ethers are of the order 10^{-12} mm., it is probable that further purification, coupled with modification of pumps, should lead to the direct production of still lower pressures. The ultimate vacuums of the present experiments were not immediately obtainable, but required treatment of the samples and generous insulation of the pumps to conserve heat and prevent charring of the bench with the higher boiling fillings. The behaviour in metal pumps and other vacuum properties of these fluids will be presented through the vacuum journals.

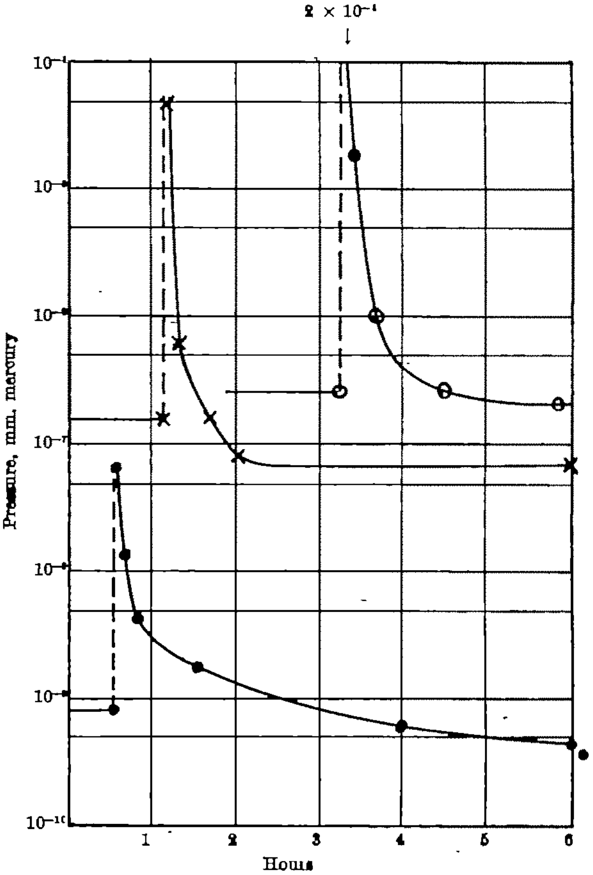


Fig. 1. ○, A petroleum base pump oil; ×, 2-ethyl hexyl phthalate; ●, *m-bis*(*m*-phenoxyphenoxy)-benzene

I am indebted to the Monsanto Chemical Co., St. Louis, Missouri, for gifts of the compounds, and to the Trans Penn Wax Corporation, Titusville, Pennsylvania, for contributory financial support. Correspondence concerning vacuum applications of the fluids may be addressed to me.

METALLURGY

The Sulphide Phase in Some Iron Meteorites

METALLIC meteorites are composed in varying proportions of two iron–nickel metallic solid solutions, kamacite, which has a low nickel content, and taenite, which has a higher nickel content. The structure and distribution of these phases have been extensively examined on a macro- and on a micro-scale. Many iron meteorites also contain non-metallic inclusions of an iron–nickel phosphide (schreibersite) or an iron–nickel sulphide (troilite). Troilite has not been subject to very detailed microscopic examination for

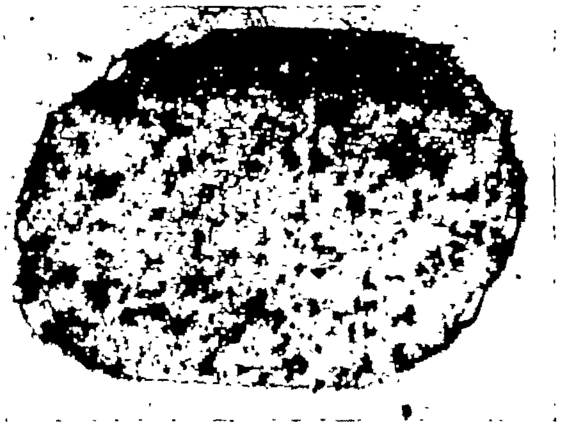

Fig. 1. Walker County unetched. (× c. 215)

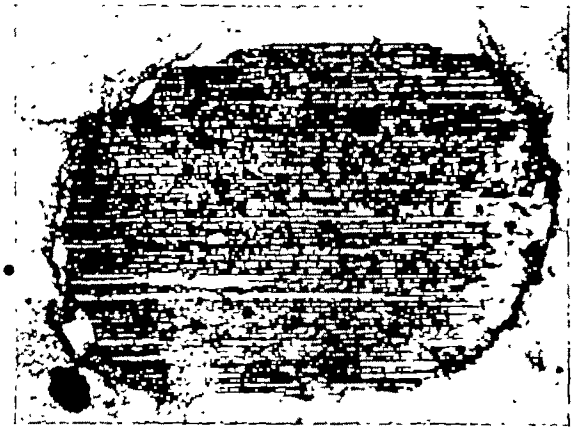

Fig. 2. Same area after sulphur printing. (× 215)

two reasons. First, it shows a great tendency to chip and disintegrate during preparation and, secondly, it is very reactive towards most etching agents; hence, when metallic meteorites are deeply etched for museum exhibition the troilite is usually protected from the etching agent by a suitable stopping-off compound.

Perry[1] has published a photograph of an anomalous lamellar structure which he found at a single location within a vein of terrestrial weathering material in the Walker County hexahedrite and which he identified as a kamacite–taenite aggregate. However, the general appearance and location seem to suggest that the structure might have arisen from a partly weathered non-metallic compound, hence a search for similar structures has been made in unweathered portions of Walker County and other hexahedrites. Several examples have been found in a small piece of Walker County loaned for study by the British Museum (*B.M.* 35413). Fig. 1 shows an area in the unetched condition. The groundmass is kamacite, in which is embedded a roughly circular brown patch of striated material. The black areas are holes due to the chipping out of material during preparation, and there are occasional patches of white schreibersite situated between the striated phase and the groundmass of kamacite. The striated phase proved to be sulphide bearing, as shown by its response to sulphur printing[2]. The same area examined immediately after sulphur printing shows the striations much more distinctly (Fig. 2) and reveals that the dark component of the striated pattern, which is undoubtedly troilite, is more heavily cracked than the light component. It is not possible at this stage to give a firm identification of the light striations.

Similar effects have also been obtained from small troilite areas in the hexahedrites Coahuila (*B.M.* 53295) and Tocopilla (*B.M.* 1931, 13). In each case the sulphide body was associated with a partial or complete rim of schreibersite.

A New Phase in a Silicon bearing 17 per cent Chromium, 8 per cent Nickel and 1 per cent Niobium Steel

During the study of a 17 per cent chromium–8 per cent nickel–4 per cent silicon–1 per cent niobium steel, the composition of which is shown in Table 1, a phase not previously reported was extracted and subjected to X-ray examination.

An X-ray diffraction pattern was obtained from the extracted residue in a 19-cm. powder camera using cobalt radiation filtered with iron foil. The interplanar spacings of the phase contained in the residue are shown in Table 2. The pattern can be indexed on a tetragonal structure having parameters $a = 4{\cdot}806$ Å., $c = 5{\cdot}955$ Å. and a c/a ratio of 1·238. The presence of gelatinous silicic acid in the residue prevented an accurate chemical analysis being performed, although it appeared that a high concentration of niobium together with some chromium,

silicon and carbon was present. The difficulty of extracting the phase under examination free from contamination by silicic acid prevented a density measurement being performed and so no space group could be assigned to the phase.

The appearance of the phase in the microstructure is shown in Fig. 1.

We wish to acknowledge that Dr. H. Hughes (United Steel Companies' Research Laboratory) pointed out the tetragonal nature of the X-ray pattern before it had been finally indexed.

CHEMISTRY

Mass Spectrometric Investigation of the Vaporization of Sulphides and the Dissociation Energy of S_2

The disagreement between second- and third-law values of the dissociation energy of $S_2(D^\circ_0(S_2))$ obtained from equilibrium measurements was emphasized many years ago[1]. A relationship was also pointed out between the heat of combustion of SO, $D^\circ_0(O_2)$, $D^\circ_0(SO)$ and $D^\circ_0(S_2)$, which should permit one to choose one of the values allowed by observed predissociations for $D^\circ_0(S_2)$ and $D^\circ_0(SO)$. Recent measurements[2] do not seem to settle the question[3].

In the vapour phase above calcium sulphide we have observed by mass spectrometry the dissociation $S_2 \rightleftharpoons 2S$, and $CaS \rightleftharpoons Ca + S$, and have calculated $D^\circ_0(S_2) = 4{\cdot}4 \pm 0{\cdot}2$ eV., $D^\circ_0(SO) = 5{\cdot}4 + 0{\cdot}2$ eV., $D^\circ_0(CaS) = 3{\cdot}0 \pm 0{\cdot}2$ eV. and ΔH°_{298}(vap., CaS) = $6{\cdot}4 \pm 0{\cdot}2$ eV.

The mass spectrometric method has been described previously[4,5]. The sample was heated in a molybdenum Knudsen cell; provisions were made for distinguishing between residual gas molecules and those of the beam, which passes through a cooled collimation system; ion intensities were measured with an electron multiplier. Absolute values of partial vapour pressures were obtained from $P_i = I_iT/S_i$; I_i is the measured current corresponding to a species i, T the absolute temperature of the Knudsen cell and S_i the sensitivity for i (ref. 6): $S_i = (M_i/2\pi R)^{1/2}(s/G_i)\Sigma I_i T^{1/2}\,\Delta t$; M_i is its molecular mass, R the gas constant, s the area of the effusion orifice and t the time necessary to evaporate the weight G_i of species i. Brightness temperatures of a small threaded hole at the bottom of the Knudsen cell have been measured with an optical pyrometer; emissivity and window corrections were made[7].

Dissociation energies were calculated from: $D^\circ_0 = -RT\ln K + T\,\Delta((F^\circ_T - H^\circ_0)/T)$ (third law) and $D^\circ_T = -R d\ln K/d(1/T)$ (second law) using free-energy functions taken from Stull and Sinke[8], or for calcium sulphide, calculated by comparison of oxides and sulphides, assuming $\omega_e = 390$ cm.$^{-1}$, $r_e = 2{\cdot}3$ Å. and that only the $^1\Sigma$ ground-state is important.

Ionization cross-sections were taken from Otvos and Stevenson[9], and it was assumed that those of molecules are equal to the sum of those of the constituent atoms. The mass effect and the molecular effect of the multiplier[10] were considered to compensate each other. A possible error of 20° in the temperature measurement would lead to an uncertainty of 12 per cent in the second-law and of 1 per cent in the third-law values; instead of the assumptions made above, it is reasonable to suggest that the product of ionization cross-section and multiplier gain is the same for the atom and for the molecule[11]: in that case the third law D°_0 values of Table 1 are increased by about + 3·5 kcal. and ΔH°_{298}(vap., CaS) diminished by the same amount.

† $[F^\circ_T - H^\circ_{298}]/T$ for this process is based on very scanty data on C_p (CaS) (Kelley, K. K., U.S. Bureau of Mines Bulletin 476, Washington (1949)).

The results in Table 1 and ΔH°_{298}(vap., Ca) (ref. 8) = 42·2 kcal., $\Delta H^\circ_{298}(\frac{1}{2}S_2)$ = 15·4 kcal., the standard heat of formation ΔH°_{298f}(CaS) = 110·0 ± 2 kcal. (ref. 12) permit one to calculate ΔH°_{298}(vap., CaS) = 147 kcal. The value obtained from this cycle is considered to be more reliable than that given in Table 1 (see note to Table 1).

$D^\circ_0(S_2)$ obtained here, combined with ΔH°_0(SO) (ref. 2b) for the reaction $\frac{1}{2}S_2 + \frac{1}{2}O_2 \rightleftharpoons SO$, definitely rules out a value D°_0(SO) smaller than 5·2 eV. There are good spectroscopic arguments for D°_0(SO) = 5·358 eV. (ref. 13) rather than 5 027 eV. (ref. 3). Our measurements are not accurate enough to permit one to settle the question whether the predissociation at 4·41 eV. gives the exact dissociation of S_2 (ref. 14) or an upper limit[15]; a value $D(S_2) = 4 \cdot 2$ eV. would agree with our results[16]. Within the accuracy quoted in Table 1, all available data on $D(S_2)$ and $D(SO)$ (ref. 3) except appearance potential measurements[17] and older equilibrium measurements (cf. refs. 1, 2, 3, 14) seem to be in agreement.

Experimental details and further data on strontium sulphide and barium sulphide will be published shortly.

Thanks are due to the Comité Belge de Spectrométrie de Masse (I.R.S.I.A.), which has made available part of the equipment. The investigation was sponsored in part by the Wright Air Development Center of the Air Research and Development Command, United States Air Force, through its European Office, under contract No. *AF* 61(052)-225.

Ionization and Attachment Coefficients in *n*-Alkyl Chloride Gases

We have measured ionization coefficients in the five *n*-alkyl chloride gases, methyl, ethyl, propyl, butyl, and amyl chloride, using an experimental apparatus similar to that described by Geballe and Harrison[1]. Despite the fact that these gases contain a halogen atom, they exhibit no detectable electron attachment to form negative ions. The present work constitutes part of an experimental programme for measuring ionization and attachment coefficients in a large variety of electronegative gases. We hope that such data will serve as a guide for the correlation of these coefficients, important to an understanding of the electrical breakdown of gases, with molecular structure.

The gases used in this work are commercially available products which, when necessary, were purified by vapour phase chromatography. We estimate the final purity of each gas to be greater than 99 per cent.

The essential part of the experimental apparatus consists of a pair of plane, parallel electrodes of 10 cm. diam., the spacing between which is variable from 0 to 3 cm. The cathode is irradiated with ultra-violet light through perforations in a 1-in. diam. area in the centre of the anode, to produce a constant primary electron photocurrent, i_0. The current to the anode, i, is measured as a function of the electrode spacing, δ, at constant field strength, E, and gas pressure, P. Pressures used varied from 1 to 40 mm. mercury.

In each of the alkyl chloride gases the current was found to vary as $i = i_0 \exp \alpha\delta$. From the absence of curvature in plots of log i versus δ over a range $0 \cdot 1 < \delta < 3$ cm., we can estimate that if negative ion formation occurs at all, the coefficient of attachment, η, must be smaller than 10–15 per cent of the observed ionization coefficient, α, at each E/P in every gas. Furthermore, in methyl chloride, for example, at $E/P = 40$, $\alpha/P = 0 \cdot 0307$ and $\eta/P \lesssim 0 \cdot 005$. Since an electron capture process, for example, $e + CH_3Cl = CH_3 + Cl^-$, is usually characterized by an η/P which varies slowly with E/P[1], an upper limit to η/P for capture processes in methyl chloride can probably be set at approximately 0·005 for all the E/P range studied.

The absence of measurable attachment is consistent with the mass spectrographic studies of methyl chloride by Dibeler and Reese[2]. They found that negative ions are not produced by capture processes, but only by a double-ion process, $CH_3Cl + e = CH_3^+ + Cl^- + e$, which has a small probability (about 1 per cent for 75-V. electrons) relative to that for the production of CH_3Cl^+ ions.

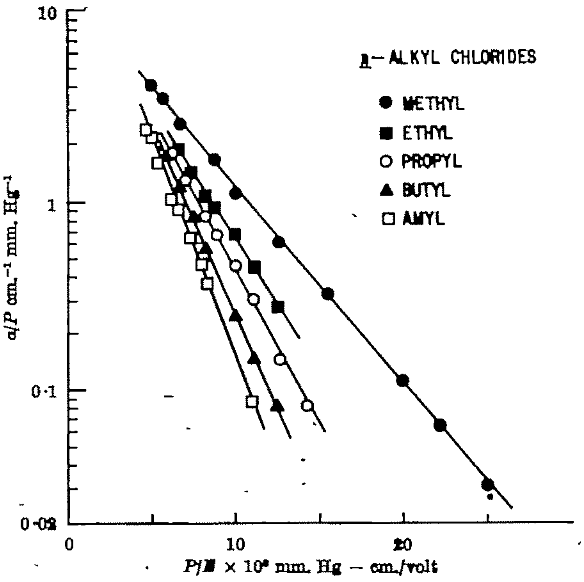

Fig. 1. Observed ionization coefficients as functions of P/E

The variation of α with E and P in the alkyl chlorides is expressed accurately by the functional form $\alpha/P = A\exp(-BP/E)$, as is illustrated in Fig. 1. It is especially to be noted that the functional form $\alpha/E = A\exp(-BP/E)$ will not fit the data. Values of the constants A and B, as derived from the curves in Fig. 1, are listed in Table 1.

Table 1

Gas	A cm.$^{-1}$ mm.$^{-1}$	B v cm.$^{-1}$ mm.$^{-1}$	ϵ_i eV.	$B/\epsilon_i^{3/2}$ cm.$^{-1}$ mm.$^{-1}$ v$^{-1/2}$
CH_3Cl	13·4	244	11·28*	6·4
C_2H_5Cl	16·1	325	10·97*	8·9
n-C_3H_7Cl	20·7	388	10·8†	10·9

‡ Estimated.

At present there exists no exact theory for the correlation of these quantities with molecular structure. The approximate theory of Crowe, Bragg and Devins[3] predicts that the constant B will vary with molecular parameters in a homologous series as $B = C\epsilon_i^{3/2}\theta$, where ϵ_i is the molecular ionization energy and θ the total cross-section for electron scattering. Devins and Crowe[4] and Heylen and Lewis[5] derived values of B for a number of saturated hydrocarbon gases from sparking potential measurements. They found that $B/\epsilon_i^{3/2}$ is directly proportional to the number of carbon–hydrogen bonds in the n-alkane gases, indicating that electrons in the carbon–hydrogen bonding orbitals (that is, the electrons in the outermost molecular orbitals) are most effective in electron scattering.

The values of $B/\epsilon_i^{3/2}$ of Devins and Crowe for the alkanes are plotted in Fig. 2 along with our values for the alkyl chlorides. From the theory, the slope of the alkyl chloride curve is proportional to the C–H bond cross-section, while the intercept is proportional to the cross-section of chlorine bonded to a carbon atom. Analysis of the data yields a least-squares line of slope 1·16 ± 0·03 and intercept 2·97 ± 0·07. The slope for the alkyl chloride data is approximately twice that for the alkanes. The largest part of this difference is possibly due to an incorrect choice for the functional form for α by Devins and Crowe. The sparking potential data cover a rather limited range of E/P, so that their data can be fitted equally well using either $\alpha/P = A\exp(-BP/E)$ or $\alpha/E = A\exp(-BP/E)$. The B values they quote were obtained using the latter form. If the former expression were used instead, all of the B values for the alkanes would be larger by a multiplicative constant of approximately 1·5. Even so, the two slopes in Fig. 2 would still be different by 25 per cent, indicating either a larger C–H bond cross-section in the alkyl chlorides or different proportionality constants for the two homologous series in the equation $B = C\epsilon_i^{3/2}\theta$.

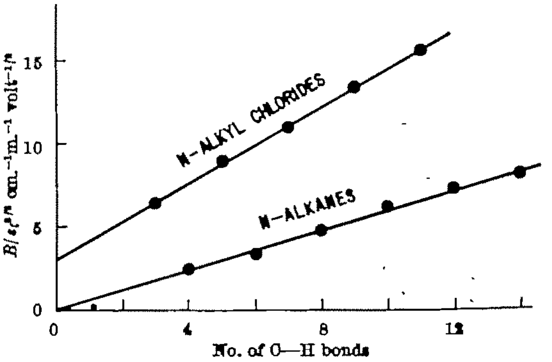

Fig. 2. Dependence of $B/\epsilon_i^{3/2}$ on the number of carbon–hydrogen bonds per molecule. Upper curve, this work; lower curve, ref. 4

The constant A in the alkyl chlorides appears to vary as $a + b(n_{C-H})^2$. The significance of this observation is not clear.

We are indebted to E. M. Hadsell for performing analyses and purifications by vapour phase chromatography.

Homogeneous Synthesis of Isotactic Polystyrene using n-Butyllithium Initiator

ORGANOLITHIUM compounds are known to cause the stereospecific polymerization of dienes[1] and methacrylates[2]. Via n-butyllithium, styrene polymerizes easily to atactic polymer at ordinary temperatures[3,4]. We have now found that styrene may be polymerized at low temperatures, employing butyllithium as a soluble initiator, to crystallizable isotactic polystyrene.

Polystyrene prepared in a hydrocarbon medium at temperatures in the range of − 30° C. and below exhibits infra-red, X-ray diffraction and nuclear spin resonance spectra identical to those shown by isotactic crystalline polystyrene prepared via triethyl-aluminium–titanium trichloride catalysis. In the presence of ethers, however, only atactic polymer forms, even at − 78° C. Isotactic polymerization is much slower at − 40° (~ 5 per cent conversion in 48 hr.) in a 7 : 1 volume ratio styrene–toluene mixture than at − 78° in tetrahydrofuran (> 90 per cent conv. in 1 hr.). Butyllithium concentrations of 5–10 m.mol./l. were used.

A block copolymer of atactic and isotactic types of polystyrene may be prepared by adding an ether to a styrene polymerization proceeding at − 40° in toluene. The same result may be achieved by raising the temperature to 0° after polymerizing for a period of time at about − 40°. Blocks of a second monomer species (such as isoprene, alkyl methacrylates and acrylonitrile) on isotactic polystyrene can be prepared even though styrene conversion is far from complete[5].

BIOCHEMISTRY

Presence of Neutral Carbohydrates in Human Aortic Tissue

In 1938, Hisamura[1] demonstrated that demineralized bone tissue contained two carbohydrate-protein fractions, a uronic acid-containing and a uronic acid-free fraction.

Consden[2] and Glegg *et al.*[3] later showed that connective tissue from different organs contains both acid mucopolysaccharides and considerable amounts of neutral heteropolysaccharides. The designation neutral heteropolysaccharides covers neutral mucopolysaccharides, containing hexosamine, and neutral monosaccharides, as well as glycoproteins which have bound hexosamine and/or various neutral monosaccharides in a firmly covalent bond to the protein. The term neutral refers only to the absence of hexuronic acids as constituents of the molecule.

Bertelsen and Jensen[4] showed in an earlier publication that the content of acid mucopolysaccharides in aortic tissue increases with age. They also found with increasing age a deposit of ground substance which—after oxidation with periodic acid—was strongly stained with Schiff's reagent.

This communication reports preliminary results obtained from experiments made in an attempt to isolate neutral mucopolysaccharides from macroscopically normal aortic tissue.

An extraction was made with 0·5 *N* sodium hydroxide for 4 days in an ice-box. The aortic tissue had already been rid of adventitia, disintegrated and defatted. After neutralization of the filtrate a precipitate was deposited in two volumes of absolute alcohol (fraction I). According to Meyer and Chaffee[5] this fraction contains the acid mucopolysaccharides. By increasing the alcoholic percentage to 84 a further precipitate (fraction II), which according to Glegg *et al.*[3] contains uronic acid-free carbohydrates, was deposited.

Table 1 shows that the ratio fraction I/II increases considerably with age. Both fractions increase, but the percentage increase of fraction I is much larger than that of fraction II.

Table 1. FRACTIONS EXPRESSED IN PERCENTAGES OF DRY, DEFATTED WEIGHT

Age	Fraction I	Fraction II
7 months	3·3	3·1
2 years	5·3	4·2
45 years	11·4	4·9
58 years	14·1	5·4
60 years	14·6	6·2

The qualitative determination of uronic acid was made by carboxylic reaction. The monosaccharides were determined by their colour reactions to cysteine, carbazol and sulphuric acid, as described by Dische[6] (Table 2). The content of hexosamine in the fractions was determined quantitatively by Blix's[7] modification of Elson and Morgan's method after hydrolysis.

Table 2

Age	Uronic acid	Hexosamine	Ketohexose	Aldohexose	PAS
Fraction I					
7 months	+	+	÷	+	(+)
2 years	+	+	÷	÷	(+)
45 years	+	+	÷	−	(+)
58 years	+	+	÷	÷	(+)
60 years	+	+	÷	+	(+)
Fraction II					
7 months	+	+	+	+	+
2 years	÷	+	+	+	+
45 years	÷	+	+	+	+
58 years	+	+	+	+	+
60 years	÷	+	+	+	+

The quantitative content of hexosamine determined in fractions I and II respectively, and converted into 100-gm. dried, defatted tissue, is given in Table 3. An unmistakable increase of the hexosamine contents with age will be observed in both fractions. The increase in percentage is by far the greatest in the fraction containing the acid mucopolysaccharides.

Table 3. HEXOSAMINE CONTENT (MGM. PER 100-GM. DRIED, DEFATTED TISSUE)

Age	Acid mucopolysaccharides	Neutral mucopolysaccharides
7 months	262	128
2 years	358	137
45 years	550	156
60 years	625	176

The periodic acid–Schiff reaction was carried out according to the method indicated by McManus and Hoch-Ligeti[8]. Fraction II showed a very strong reaction, whereas fraction I only showed a faint reaction. There was a distinct difference between the ways in which the fractions were soluble in water. Fraction I proved slowly soluble, forming fairly viscous solutions; whereas fraction II was quickly soluble, with a viscosity similar to that of water.

The preliminary result shows that with increasing age a considerable deposit of mucoid substance occurs in aorta; acid mucopolysaccharides, forming the mucoproteins, and neutral mucopolysaccharides, forming glycoproteins similar in nature to serum proteins.

The increase of acid mucopolysaccharides is greater than the increase of glycoproteins, which is in complete agreement with the histological picture.

Histochemical experiments made on aortic tissue, concurrently with the biochemical experiments, were found to be in agreement with the abovementioned results. A big increase in the content of acid mucopolysaccharides, starting even in childhood, was found. The deposit of periodic acid–Schiff-positive substance was not distinct in the adult aorta until after the second decade, and then it increased gradually with the years.

Organic Matrix of Tooth Enamel

LITTLE is known about the chemical nature of the organic matrix of enamel, although it presumably plays an essential part in the initiation and organization of the growth of hydroxyapatite crystals. The mature enamel finally resulting from these processes is the hardest and most highly mineralized of vertebrate tissues. Other mineralized tissues, bone[1] and dentine[2], contain 15–26 per cent of persistent organic matrix, at least 90 per cent of which is collagen. Mature human enamel contains only some 0·6 per cent of organic matter and 0·36 per cent of proteins, approximately half of which are soluble in acid decalcifying fluids[3]. Investigations of the composition of enamel proteins have been largely confined to insoluble residues from the demineralization of the mature tissue[3–5]. A recent finding, in this laboratory, that partly mineralized enamel from developing teeth in the human fœtus contains approximately 20 per cent of material of protein character was followed by a preliminary investigation of its amino-acid composition.

The upper central incisors were carefully removed from a 33-week old fœtus and the calcified caps, which consist of both enamel and dentine, were freed from soft tissues. The tooth caps were gently wiped with cotton wool, slightly moistened with saline solution, to remove traces of blood. The enamel was readily removed from the underlying dentine by gently chipping with a dental excavator, the procedure being carried out under an ophthalmic operation microscope. The enamel was thereby reduced to a white crystalline powder, which had a somewhat waxy texture and showed evidence of prism structure with the optical microscope. The enamel was dissolved in 6 *N* hydrochloric acid and the solution heated at 100° C. for 48 hr. to hydrolyse any proteins. After removal of the hydrochloric acid, the amino-acids were determined by a semi-micro, resin chromatographic method[6], loads equivalent to 0·8 mgm. of protein being transferred to 0·4-cm. diameter 'Dowex 50' columns.

The results, expressed as numbers of amino-acid residues per thousand total residues, are summarized in Table 1. No peaks were observed corresponding to hydroxyproline and hydroxylysine, which are characteristic constituents of collagen. It was concluded that no collagen was present and that the enamel had been adequately separated from dentine. The composition differed markedly from collagen[7], epidermal 'keratin'[8], elastin[9], blood proteins[10] and the insoluble proteins of mature enamel[3–5]. The overall composition was very characteristic and no similar results for another protein have so far been found in the literature. Characteristic features are: (1) proline accounts for one-quarter of the total residues; (2) the high ratio of glutamic to aspartic acid; (3) histidine is the predominant basic amino-acid; (4) tyrosine greatly exceeds phenylalanine; and (5) the high methionine content.

Table 1. AMINO-ACID COMPOSITION OF DEVELOPING ENAMEL AND INSOLUBLE PROTEIN FROM MATURE ENAMEL

(Values are given as numbers of amino-acid residues per thousand total residues)

	Developing enamel from human fœtus	Acid-insoluble residue from mature human enamel

Hydroxyproline	0	47·3
Hydroxylysine	0	—
Amide	146	—

The most complete data for the insoluble protein from mature enamel due to Hess *et al.*[4] (Table 1) are in reasonable agreement with the results of Battistone and Burnett[5] but show differences from those of Stack[3]. All three analyses, however, revealed significant amounts of hydroxyproline which, together with the glycine and alanine values, suggest that collagen is present. The cystine, serine and basic amino-acid values are compatible with the presence of an epithelial keratin, similar to that found in epidermis[8], in addition to collagen. The increased quantity of cystine found in the cuticle of enamel[11] may indicate that the protein of epidermal type is associated with the epithelial layer.

The existence of a high proportion of amino-compounds in hydrolysates of partially mineralized enamel suggests the original presence of proteins rather than free amino-acids or small peptides. The amino-acid composition of developing enamel differs remarkably from that of the insoluble protein fraction from mature enamel (Table 1). It is considered that this difference results from the developing enamel containing one or more proteins associated with the true enamel matrix, in which hydroxyapatite crystals are formed. The large differences in composition suggest that the matrix protein accounts for a substantial proportion of the total protein of developing enamel. It is not surprising that the matrix protein should be unlike the keratins in composition since it is secreted by highly active ameloblasts, whereas the epithelial keratins result from cell degeneration. The decrease in protein content from 20 per cent in fœtal enamel to 0·36 per cent in the mature tissue, together with the change in composition, suggest that the matrix protein is removed either during maturation of enamel, after eruption of the teeth or during subsequent aqueous extraction of the ground enamel. Removal of organic matrix in the later stages of enamel development would seem to be consistent with, and may be essential for, the attainment of a high degree of mineralization. This view is supported experimentally by the widespread finding that in sections of teeth decalcified with strong acids, structure attributable to the enamel matrix is visible in the earlier stages of tooth development, whereas mature enamel is completely dissolved. A transition from one stage to the other has been observed in continuously growing teeth[12].

Starch-like Polysaccharide of *Streptococcus pyogenes*

MANY strains of Lancefield group *A* streptococci synthesize a starch-like polysaccharide when grown on a medium containing maltose or maltose-polymers[1], and some of these strains also produce an extracellular amylase[2]. It has been shown that amylase-negative starch-accumulating strains are associated with acute glomerulonephritis and acute rheumatic fever[3]. There is as yet no direct proof that the starch itself is more than a metabolic marker of bacterial variants, but because of the possibility of its production *in vivo* its isolation and characterization were of considerable interest, for it has been shown that bacterial polysaccharides of high molecular weight may have long persistence in the tissues[4].

The group *A* strain, *IRP* 118, type 19, was grown in 15 litres brain–heart–infusion broth, with repeated additions of maltose and automatic adjustment to pH 7·4 during 48 hr. Thrice-washed cell suspensions (about 40 gm. dry weight) were extracted for 1 hr. at 0° with 400 ml. perchloric acid. The final perchloric acid concentration used differed in different experiments, but although the yield of polysaccharide was greater with 5 N acid than with 2 N acid, the properties of the products were very similar. After clarifying by centrifugation, the extract was carefully neutralized at 0° with sodium hydroxide to pH 6·0. On saturation of the neutralized extract with n-butanol and allowing to stand for two days at 0°, a small amount of a white precipitate appeared at the interface, but this did not stain with iodine and was therefore discarded.

The polysaccharide was then precipitated as a complex with iodine, iodine (0·1 N) in potassium iodide (0·3 N) being added to the aqueous layer until no more blue precipitate appeared and the supernatant solution was just yellow with excess iodine. (Further addition of iodine produced a brown turbidity.) The purple precipitate was washed with dilute iodine solution and then suspended in warm distilled water and just decolorized with dilute sodium thiosulphate. The polysaccharide was then precipitated from this solution by successive additions of acetone at 0°, the bulk of the iodine-staining material being precipitated between 35 per cent and 45 per cent v/v acetone. The product was washed with n-butanol and then with acetone and ether. The amorphous white powder thus obtained was poorly soluble in water, and solutions were best obtained by dissolving in 0·3 N sodium hydroxide and only neutralizing immediately before use.

It was shown by paper chromatography that the sole sugar produced by acid hydrolysis[5] of the product was glucose. Reducing-sugar estimation[6] after acid hydrolysis, however, showed that the product was only 95 per cent polysaccharide, the remainder being apparently inorganic salts. When calculations were based on the polysaccharide content it was found that hydrolysis with salivary α-amylase resulted in a 100 per cent yield of maltose (as estimated by the method of Somogyi[6]) and 100 per cent hydrolysis based on iodine stain. With a commercial sample of purified β-amylase, 98 per cent maltose was liberated and the optical density of the iodine stain[7] fell to 3 per cent of its original value. Since the residual iodine stain was always of the same quality as that of the original material, it seems likely that this discrepancy was due to partial retrogradation. The 'blue value'[8] of the product varied from preparation to preparation as did the yield. For example, one preparation of 60 mgm. polysaccharide from 38 gm. dry weight cells had a 'blue value' of 0·65, and one of 200 mgm. from 49 gm. cells had a 'blue value' of 0·8. Controlled retrogradation of the latter product gave fractions with 'blue values' of 0·87 and 0·75 respectively and a trace of a red-staining fraction.

None of these fractions, however, showed any significant limit to β-amylolysis. It therefore seems that the polysaccharide extractable from this culture by perchloric acid is of the purely straight-chain amylose type with a range of chain-lengths from about 40 to 60 glucose units. (Based on 'blue values' for linear dextrins (Whelan, W. J., private communication).) This is confirmed by the fact that the product is completely hydrolysed when incubated in the presence of excess glucose with a preparation of amylomaltase obtained from the same strain of group *A* streptococcus according to the method of Monod and Torriani[9] for the amylomaltase of *E. coli mutabile* (*ML*).

Although the polysaccharide isolated does not have a very high molecular weight it exhibits a great tendency to retrograde and this retrograded form is very insoluble and might be expected to persist for long periods if it was in fact ever formed in tissues.

Ubiquinone (50) and Ubichromenol in *Aspergillus fumigatus*, Fresenius

FOLLOWING the recent discovery[1–3] of a series of ubiquinones in various biological tissues, a useful system for studying their biosynthesis was sought. A strain of *Aspergillus fumigatus*, Fresenius (we wish to thank Prof. J. H. Birkinshaw for the gift of a specimen culture), studied by Anslow and Raistrick[4], was observed to secrete 3-hydroxy, 4-methoxy, 2,5-toluquinone (fumigatin) into the medium. This compound is closely related to the ring nucleus of ubiquinone and it seemed possible that the above organism might also produce sufficient ubiquinone for the study of its biosynthesis.

Cultures of the fungus were grown at 30° in Roux bottles, each containing 200 ml. Raulin–Thom medium at pH 3·8. After various intervals from 3 days to 8 weeks, the thalli from groups of 2 bottles were removed and examined for ubiquinone. In the preliminary experiments, the tissue was saponified directly in methanolic potassium hydroxide in the

Table 1. THE STIMULATORY EFFECT OF LEUCINE ON THE SYNTHESIS OF UBIQUINONE (50) AND UBICHROMENOL IN *Aspergillus fumigatus* FRES-

There were three Roux bottles in each experimental group but the yields after 7 days growth are expressed per bottle containing 200 ml. Raulin–Thom medium with initial $pH = 3·8$.

* The ether extract consists mainly of substituted quinones of which a variable fraction is fumigatin. There were approximately 80 mgm. fumigatin in each bottle of control medium.

presence of pyrogallol, and the unsaponifiable matter extracted with ether. In the later work, the lipids were extracted directly from the thalli using acetone, alcohol and ether in turn. The unsaponifiable material or the lipid extract was then chromatographed on a column of partially deactivated, acid-washed alumina (Brockmann Grade III) by a standard procedure[7] for ubiquinone.

A pale yellow zone with the same chromatographic behaviour and absorption band as ubiquinone ($\lambda_{max.}$ 272 mμ in *cyclo*hexane) was eluted from the column. A second chromatography on a column of silicic acid/'Celite' (2 : 1 w/w) enabled ubiquinone to be obtained from pooled samples in crystalline form. It had the following properties which are characteristic of ubiquinone (50)[3]: m.p. 48·5° C. (uncorr.), $E(1\%, 1 \text{ cm.})$ 272 mμ = 168, infra-red spectrum identical with that of ubiquinone (50). Chemical analysis gave percentages carbon, hydrogen and oxygen of 81·62, 10·90 and 7·47 respectively compared with theoretical values of 82·04, 10·42 and 7·54. The methoxyl contents of two different samples were 7·38 and 7·21 per cent respectively, which also agree with the theoretical 7·19 per cent for ubiquinone (50) within experimental error. The dry weight of the thallus and ubiquinone content (0·6 μmol./gm. dry wt.) were maximal after 7–10 days growth and declined thereafter.

This level of ubiquinone is comparable with that in animal tissues and some yeasts[5]. Ubiquinones from the latter, however, generally possess shorter isoprenoid side-chains with 30–45 carbons.

From the aqueous medium, fumigatin[6] and another quinone, believed to be spinulosin (3,6-dihydroxy-4-methoxy 2,5-toluquinone), have been isolated. The formation of these, however, can be reduced or suppressed by adding *l*-leucine to the culture medium. At the same time, the organism is stimulated to make a larger amount of ubiquinone and also its cyclic isomer, ubichromenol[7,8] (Table 1). Ubichromenol was first isolated from animal tissues, but it can also be produced artificially by the adsorption of ubiquinone on very strong alumina[4]. The material found in *Aspergillus fumigatus* is not an artefact, because it was obtained from the tissue by direct extraction with organic solvents and resolved from ubiquinone by a chromatographic procedure known to be incapable of converting ubiquinone into ubichromenol.

The amounts of ubichromenol available from the fungus were insufficient to permit full chemical analysis, but its ultra-violet absorption spectrum in ethanol and the isosbestic points for the bathochromic shift with alkali are identical with those of the pure material isolated from human kidney tissue. Furthermore, both show the same R_F value on reversed-phase chromatography. It is therefore reasonable to assume that the ubichromenol isolated is isomeric with ubiquinone (50).

The table of results shows clearly that the reduction in output of free quinone from the thallus in the leucine-supplemented medium more than accounts for the absolute increase in ubiquinone (50) and ubichromenol. So the leucine is altering the pattern of metabolism of the mould in a more fundamental way than merely providing a readily available pool of isoprenoid units for the synthesis of the side-chain molecules which become coupled to the nucleus.

Fumigatin and ubichromenol may be related to intermediates in the biosynthesis of ubiquinone.[9] Full details of this work and experiments with ^{14}C-labelled substrates will be published elsewhere.

Bradykinin-releasing Factor from *Bothrops jararaca* venom

IT was first shown by Rocha e Silva, Beraldo and Rosenfeld[1] that the venom of the snake *Bothrops jararaca* contains a bradykinin-releasing substance. Holtz and Raudonat[2] verified that the bradykinin-releasing substance is precipitated with ammonium sulphate at the level of 60 per cent, is independent of the proteolytic activity on hæmoglobin and accompanies the coagulating activity. Hamberg and Rocha e Silva[3] observed that the bradykinin-releasing factor is heat-resistant and that the decrease of its activity in presence of prolonged heating is parallel to that of the coagulating activity and to the fall of esterase activity on L-benzoylarginine methyl ester.

Table 1

Fraction	Coagulating specific activity†	L-Benzoyl-argine amidase specific activity†	µgm. bradykinin* released per 100 µgm. protein
1	143	1,196	40
2	609	65	70

* Standard preparation of bradykinin (3 units/mgm.).
† As described by Henriques, Fichman and Henriques (ref. 6).

Recently, Contzen, Holtz and Raudonat[4] found that the bradykinin-releasing substance is dialysable and ultra-filtrable, being independent of the coagulating factor but being accompanied by the hydrolysing activity on L-benzoyl-arginine methyl ester.

In the experiments reported here we have attempted to discover if the bradykinin-releasing activity is connected to the coagulating or to the L-benzoyl-arginine amidase activity of the venom and also to purify the bradykinin-releasing substance. In a first experiment a purified enzyme obtained from the venom of *Bothrops jararaca*, the *Bothrops* protease *A* (ref. 5), which is highly active on L-benzoyl-arginine amide, and a partially purified preparation of the coagulating factor, obtained by precipitation with ammonium sulphate[6], were studied. Table 1 shows that the bradykinin-releasing factor is independent of *Bothrops* protease *A*, its activity being higher in the fraction that has the strongest coagulating activity. In fact fraction 1, which is about 18 times as active as fraction 2 in its hydrolysing activity on L-benzoyl-arginine amide, liberated less bradykinin than fraction 2. On the other hand fraction 2, which is about four times as active as fraction 1 in its coagulating activity, is about twice as active as fraction 1 in its bradykinin-liberating activity. In another experiment a more active preparation of coagulating factor obtained by ammonium sulphate precipitation followed by electrophoresis on a starch column[6] was found to be less active as a releaser of bradykinin than the crude venom used for the same preparation. It can be seen (Table 2) that the coagulating specific activities found were 357 and 1,000 respectively for the crude venom and the purified preparation, while the crude venom liberated 100 µgm. of bradykinin and the preparation 50 µgm. of bradykinin per 100 µgm. of protein. It was therefore concluded that the bradykinin-releasing activity is independent of the *Bothrops* protease *A* and coagulating activities of the venom. This does not exclude, however, the possibility that the bradykinin-releasing substance has some amidase or esterase activity, but if so it must be certainly weaker than that of *Bothrops* protease *A*.

Table 2

Fraction	Coagulating specific activity	µgm. bradykinin released per 100 µgm. protein
Crude venom	357	100
Coagulating	1,000	50

Table 3

Fraction	Percentage of saturation with ammonium sulphate	Amidase specific activity	µgm. bradykinin released per 100 µgm. protein
1	Crude venom	27	30
2	0·45	5	—
3	0·55	9	—
4	0·60	24	—
5	0·70	72	90
6	0·80	208	240
7	1·0	35	15

Table 3 shows the experiment in which attempts were made to purify the bradykinin-releasing factor. The preparation was made by heating the venom and fractionally precipitating the supernatant with ammonium sulphate as previously described for *Bothrops* protease *A* (ref. 5). All the fractions were dialysed against saline for 48 hr. and then tested for its bradykinin-releasing activity. The fraction precipitated at the level of 0·70–0·80 saturation with ammonium sulphate contained the peak of the activity, being eight times as active as the crude venom used for the preparation, that is, 100 µgm. of protein of crude venom liberated 30 µgm. of bradykinin while the same amount of protein from the fraction liberated 240 µgm. of bradykinin. The peak of activity of the bradykinin-liberating substance coincides with the peak of activity of *Bothrops* protease *A*, but as was shown above, the two activities are independent. Also in our conditions the bradykinin-releasing factor was not dialysable as observed by Contzen, Holtz and Raudonat[4].

Anti-Pneumococcus Type XIV Activity of Precipitins from *Ricinus communis* Seeds

A CHEMICAL structure closely similar to type XIV pneumococcus polysaccharide is probably the basic substrate used in the formation of the human A, B, H and Le^a blood group specific substances[1]. Studies of the precipitation of the various blood group specific substances and related materials by *Ricinus communis* seed extract suggest that the activity of the *Ricinus* precipitin is directed towards the basic chemical framework of the human blood group substances[2–4]. It is thus possible that the *Ricinus* precipitin is actually specific for type XIV pneumococcus polysaccharide. The following experiments were carried out to investigate this possibility.

Purified pneumococcal polysaccharides of type II, VIII, IX, XII, XIV and XVII were made up as 1/1,000 (w/v) aqueous solutions and tested by the conventional precipitation technique against *Ricinus communis* seed extract prepared by the method of Boyd and Reguera[5], clarified by filtration through Whatman No. 42 filter paper and sterilized by Seitz filtration. Only type XIV polysaccharide was precipitated (Table 1).

Table 1. PRECIPITATION OF PNEUMOCOCCAL POLYSACCHARIDES BY *Ricinus communis* EXTRACT

Polysaccharide	Dilution			Controls
	1/1,000	1/10,000	1/100,000	
Type II	0	0	0	0
VIII	0	0	0	
IX	0	0	0	
XII	0	0	0	
XIV	3	1	tr	
XVII	0	0	0	

3, 1, denote degrees of precipitation ; tr, trace ; 0, no precipitate ; controls, extract + saline, polysaccharide + saline.

The type XIV polysaccharide was allowed to diffuse in an Ouchterlony agar-gel plate[6] against *Ricinus* extract and horse anti-XIV serum. The precipitins present in the extract and in the serum gave a "reaction of identity"[4] ; this means that the *Ricinus* precipitin and the specific precipitin for type XIV pneumococcus precipitate the same substance.

Thus there is evidence that the activity of *Ricinus communis* precipitin is directed towards the structural configuration of the type XIV pneumococcus polysaccharide. Because it was not possible to test a complete series of more than seventy known types of pneumococcal polysaccharides, it cannot as yet be claimed that the *Ricinus communis* precipitin, in this system, is exclusively specific for type XIV ; it is anticipated, however, that this will prove to be so, and that *Ricinus communis* seed extract will specifically agglutinate suspensions of type XIV pneumococci. I intend to complete this study by testing all known serological types of pneumococcus and purified preparations of their specific polysaccharides. The difficulty in obtaining all these materials is such that the project will take much time ; it is therefore considered useful briefly to direct attention, at the present stage, to the relationship of the *Ricinus communis* precipitin to specific antibody to type XIV pneumococcus.

I am indebted to the State of New York Department of Health (Division of Laboratories and Research), Albany, New York, for the pneumococcal polysaccharides and horse anti-XIV serum.

Enzymatic Synthesis of Formylglutamic Acid by a Plant Protein

SILVERMAN *et al.*[1], working with refined enzyme systems from hog liver, found indications that folinic acid functions directly only in the formylation of glutamate, with N-formylglutamic acid and tetrahydrofolic acid as the products. This communication reports the occurrence of a similar transformation in cell-free systems prepared from plant tissues.

Enzymatically active protein was obtained from mustard leaves. 2·5 kgm. of plant tissue were homogenized in an ice-cold solution of acetone and phosphate buffer *p*H 7·2 (v/v) in a Waring blendor. The solids were collected by filtration. Acetone was removed under vacuum and the residue extracted with 500 ml. of 0·02 *M* phosphate buffer *p*H 7·2. The precipitate which formed during the reduction of the volume to 250 ml. by pervaporation was removed by centrifugation and discarded. 7 gm. of ammonium sulphate were added per 100 ml. of the cell-free suspension (10 per cent of saturation at 0° C.). The precipitate was discarded. The supernatant received 14 gm. ammonium sulphate per 100 ml. (20 per cent of saturation). This precipitate was also discarded. The precipitate resulting from the treatment with 21 gm. ammonium sulphate per 100 ml. solution (30 per cent of saturation) was retained as the crude enzyme preparation. This crude product was suspended in water and dialysed for 24 hr. against 20 vol. 0·02 *M* phosphate buffer at *p*H 7·2.

Each biosynthesis medium contained 3·4 mgm. of the refined protein fraction ; 0·2 μmole each of synthetic folinic acid, adenosine triphosphate, magnesium chloride, triphosphopyridine nucleotide, and a potential formyl group acceptor in buffer to a total volume of 3 ml. In addition to glutamic acid, glycine was used for comparison purposes. After incubation at 30° C. for 4 hr., 1 ml. was withdrawn and added to 1 ml. of 4 per cent perchloric acid. The resulting precipitate was removed and the supernatant was allowed to stand at room temperature for 30 min. to allow conversion of unused folinic acid to anhydrofolinic. The latter was determined spectrophotometrically at 360 mμ. The amount of folinic acid utilized was calculated by taking the difference in absorption between biosynthesis and a control containing denatured protein. This difference was referred to a standard curve prepared with synthetic folinic acid, since the optical density of anhydrofolinic at 360 mμ was found to be a linear function of folinic acid concentration. The results are presented in Table 1.

Table 1. TRANSFORMYLASE ACTIVITY OF A PLANT PROTEIN FRACTION IN PRESENCE OF SYNTHETIC FOLINIC ACID

* For composition see text.

Separation of the biosynthesis product from the mixture containing glutamate by existing methods resulted in the isolation of a compound which was bound by chromotropic acid, under testing conditions similar to those described by Frisell *et al.*[2], and which reacted negatively with ninhydrin. After mild acid hydrolysis, the product was ninhydrin positive and formed a benzoyl derivative which melted at 135–137° C. (lit. for glutamic acid, 138° C.). Comparison indicated that the biosynthesized product was identical with a synthetic sample of formylglutamic acid. Glycine treated similarly did not become ninhydrin-negative and the product was not bound by chromotropic acid. However, the amount of unreacted folinic acid in each case diminished, indicating deformylation activity. These reactions were reversible in the absence of potential formyl group acceptors and in the presence of formaldehyde and tetrahydrofolic acid. Results obtained by separate experiments show that glycine is converted into serine by this protein fraction in the presence of synthetic folinic acid. This is in substantial agreement with Wilkinson and Davies[3], who reported that tetrahydrofolic acid appears to be a requirement for serine-glycine interconversion in plant tissues. Thus, at least two types of formylation activity are demonstrated by these results; one in which the amino-group of glutamic acid is acceptor and the other in which the 2-C of glycine is acceptor.

Further purification of the protein fraction should make it possible to obtain more information about the specificities of the transformylases occurring in plant tissues, and thus permit a more detailed study of the possible role of formylglutamic in C-1 metabolism.

This work was supported in part by a National Institutes of Health Grant No. C-1552.

Crystallization of a Photosynthetic Reductase from a Green Plant

WE would like to describe a method for crystallizing the protein now known as photosynthetic triphosphopyridine nucleotide reductase[1], formerly known as the methaemoglobin reducing factor for chloroplasts[2].

The reductase was prepared from frozen parsley (*Petroselenium sativum*) leaflets in May, following the procedure of San Pietro up to the preparation of an extract from the acetone precipitate. 4 kgm. parsley were used. After removing suspended matter the clear fluid, pH 8 in 0·005 *M tris* buffer, was chromatographed on a column of Whatman anion exchanger powder *DE* 50, 3·3 cm. diam. × 6·5 cm. This gave a narrow brown band at the top of the column, while yellow colour passed through. The column was washed with *tris* buffer (0·05 *M*, pH 8), followed by 0·2 *M* sodium acetate buffer, pH 5·5, until the washings were colourless and free from protein. The brown protein was then completely eluted with *M* acetate buffer, pH 5·5, giving 100 ml. of coloured solution. This was dialysed against 0·005 *M tris* buffer, pH 8, at 0° C. with stirring for 2 hr. and the 180 ml. solution passed through a second *DE* 50 column, 1 cm. × 3 cm. The column was washed with 0·05 *M tris* buffer, pH 8, followed in turn by 0·2 *M*, 0·5 *M* and 0·8 *M* acetate buffers, all at pH 5·5. The brown protein then occupied nearly all the column. Elution was carried out as before with *M* acetate buffer pH 5·5, giving 13 ml. of dark red-brown solution. This was then dialysed against half-saturated ammonium sulphate solution buffered with 100 ml. 0·33 *M* phosphate buffer at pH 6·7 (2 litres total volume) overnight at 0° C. The more concentrated solution, now 5·5 ml., was clarified in a centrifuge. The clear fluid was then treated with 0·15 ml. 5 per cent v/v acetic acid, when a faint turbidity appeared. After standing at 0° C. for 10 min. a precipitate was formed, consisting of minute spherical hedgehog crystal aggregates which later could be spun down in the centrifuge to a volume of about 0·5 ml. The crystal pellet was dark pinkish-brown and the liquid nearly colourless. Examination of the freshly formed crystal mass showed the crystals to be coloured, with virtually no accompanying insoluble material. This preparation was not suitable for photography as the crystals radiated in three dimensions. Crystals were therefore allowed to form on a slide under a cover glass, giving flat rosettes otherwise identical in appearance with those formed in the bulk of the solution. The crystals appeared to be plate-like as in Fig. 1*a* and more or less elongated as in Fig. 1*b*. The crystallization was repeated by dissolving the first pellet in 0·8 ml. disodium phosphate (0·05 *M*). 1 ml. saturated ammonium sulphate solution was then added and the solution spun. A small, pale precipitate was rejected. 5 per cent acetic acid was added as before to the clear fluid. Now the rosettes were mainly replaced by free crystal forms; minute elongated plates (10μ), thin plates and fine needles up to 150μ long were observed.

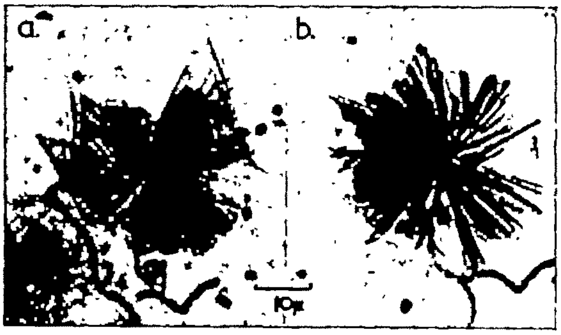

Fig. 1

This protein may be said to occupy a key position in the observed reducing properties of illuminated chloroplasts[3].

This investigation forms part of a programme of work supported by the Agricultural Research Council. We are very grateful to Prof. J. D. Boyd and to Mr. J. A. F. Fozzard for the microphotographs.

PHYSIOLOGY

Differential Reactivity of Saliva from 'Tasters' and 'Non-Tasters' of 6-*n*-Propylthiouracil

IN a previous publication[1] a difference in reactivity between the saliva of 'tasters' and 'non-tasters' towards 6-*n*-propylthiouracil was reported. This communication attempts further to describe the above phenomenon and to relate the data thus obtained to the mechanism of taste in general and to taste-blindness in particular.

A 20-min. sample of mixed morning saliva stimulated by rubber band was centrifuged at +4° C. for

Table 1

No.	Compound	'Δ optical density 8-min' effect at λ_{max}	Δ optical density at molecular concentration of compound	Taste blind differentiator	Taste quality at $1 \cdot 5 \times 10^{-3}$ M concentration	Antithyroid activity
1	6-*n*-Propylthiouracil	+	$3 \cdot 75 \times 10^{-4}$	+	bitter	+
2	2-Mercapto-imidazole	+	$3 \cdot 75 \times 10^{-4}$	+	bitter	+
3	1-Methyl-2-mercapto-imidazole	+	$3 \cdot 75 \times 10^{-4}$	+	bitter	+
4	2-Mercapto-5-carbomethoxy imidazole	—	$3 \cdot 75 \times 10^{-4}$	—	bitter	—
5	2-Mercapto-4 (or 5)-imidazole carboxylic acid	+	$3 \cdot 75 \times 10^{-4}$	—	sour	—
6	1-Methyl-2-mercapto-5-imidazole carboxylic acid	+	$3 \cdot 75 \times 10^{-4}$	—	bitter	—
7	Creatinine	—	$1 \cdot 5 \times 10^{-1}$	—	bitter*	+
8	Imidazole	—	$6 \cdot 0 \times 10^{-4}$	—	bitter	?
9	Quinine	—	$1 \cdot 5 \times 10^{-4}$	—	bitter	—

* Bitter taste quality only from 16–32-fold or higher concentration.

30 min. at 3,000 r.p.m. The supernatant was re-centrifuged and 1-ml. portions of it were diluted 1 : 5 with *tris* buffer to *p*H 7·36 at 23° C. and supplemented with 6-*n*-propylthiouracil; final concentration of *tris* and 6-*n*-propylthiouracil are 0·05 M and $3 \cdot 75 \times 10^{-4}$ M. Later, the rate of reaction in a sample was followed in a Perkin-Elmer 'Spectracord 4000-*A*' spectrophotometer at 17°, 27° and 37° C. in the ultra-violet range. The decrease in optical density was read at the λ (maximum) between 276 and 284 mμ in 8 min. This decrease, which is not photosensitive, indicates a significantly faster rate of reaction for extreme 'non-tasters' than for 'tasters' (Fig. 1).

The 'Δ optical density 8-minute' effect can be simulated in the absence of saliva by the action of hydrogen peroxide on 6-*n*-propylthiouracil. The decrease in optical density thus produced, however, increases with increasing temperature, which effect is the converse of that obtained with saliva.

The *p*H dependence of the reactivity ('Δ optical density 8-minute' effect) of saliva with 6-*n*-propylthiouracil is depicted in Fig. 2.

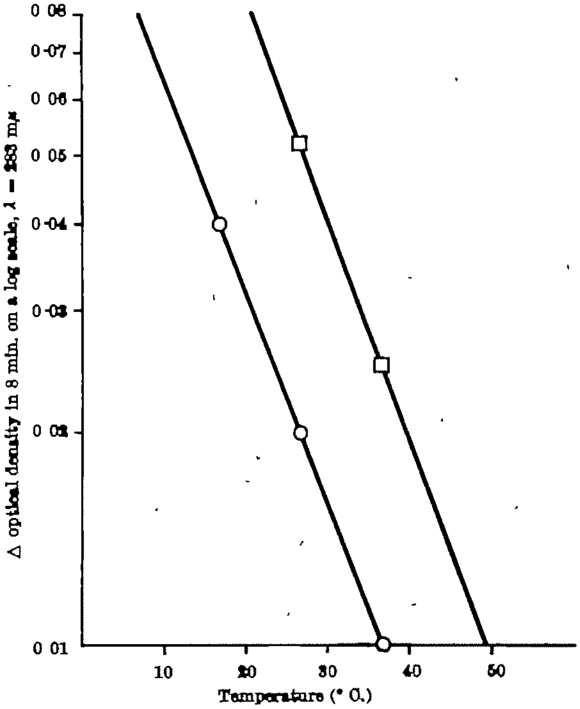

Fig. 1. Temperature dependence of the differential reactivity ('Δ optical density 8-min.' effect) of the saliva of a typical 'taster' and typical 'extreme non-taster' toward 6-*n*-propylthiouracil from a population of 32 subjects. ○ and □ represent results obtained from salivas of donors with taste-thresholds of $4 \cdot 7 \times 10^{-6}$ M and $6 \cdot 0 \times 10^{-3}$ M 6-*n*-propylthiouracil respectively

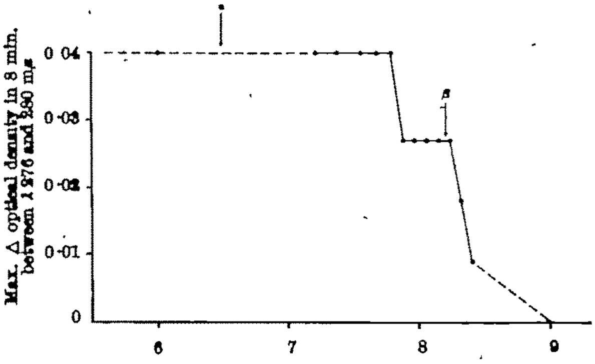

Fig. 2. *p*H dependence of the reactivity of a typical 'taster's' saliva with 6-*n*-propylthiouracil at 17° C. *Tris* buffer from *p*H 7·2–9; cacodylate buffer below *p*H 7·2

The sites α and β on the slopes of the curve approximate the *pK*(OH) values of the mono- and diiodo-derivatives of L-tyrosine. These thyroxine precursors, in fact, do lower at least 4–8- or even 32-fold the taste threshold of a subject towards 6-*n*-propylthiouracil if administered simultaneously. Specifically, 3×10^{-3} M 3-monoiodotyrosine and $7 \cdot 5 \times 10^{-4}$ M tyrosine or 3,5-diiodotyrosine have been used as solvents as well as placebos in the Harris and Kalmus[8] procedure. The actual originally defined 6-*n*-propylthiouracil threshold of the subject was a determining factor of the ability of monoiodotyrosine and/or diiodotyrosine to increase taste acuity towards 6-*n*-propylthiouracil. (The original 6-*n*-propylthiouracil threshold can also be altered by simply raising the temperature of the solution of the substance to 40° C.) Taste acuity of tasters with a $3 \cdot 75 \times 10^{-4}$ M 6-*n*-propylthiouracil threshold was increased with any of the three thyroxine precursors.

A similar increase in taste acuity towards quinine was produced under identical conditions. Only diiodotyrosine was capable of lowering thresholds of $1 \cdot 5 \times 10^{-3}$ M concentration of 6-*n*-propylthiouracil. None of the precursors was effective at threshold $6 \cdot 0 \times 10^{-3}$ M of 6-*n*-propylthiouracil, that of 'extreme non-tasters'.

Among the bitter-tasting anti-thyroid compounds which contain the thiocarbamide grouping, taste-blind differentiators other than 6-*n*-propylthiouracil also exhibit the 'Δ optical density 8-minute' effect. This effect alone, however, does not convey the quality of a taste-blind differentiator to a compound of the thiocarbamide type. Compounds No. 5 and 6 in Table 1 exemplify our contention. Another more tentative conclusion can be drawn from Fig. 1 in the light of additional (unpublished) results: anti-thyroid compounds of the thiocarbamide type with no taste-blind differentiating quality, such as creatinine (synthesized via creatine (*Org. Synthesis*, 4, 15; 1925); such a creatinine is free of picric acid, which is present in commercially available preparations. No. 7 in Table 1), an isosterically substituted thiocarbamide, are likely to produce their anti-thyroid activity[2] through another mechanism than that characteristic for compounds No. 1, 2 and 3.

Biochemical, genetic, pathophysiological and psychological aspects of the part played by thyroxine and its precursors in the mechanism of taste and 'taste-blindness' are under study and will be published elsewhere.

This work was carried out with the technical assistance of Edwin L. Mead. The active interest and helpful suggestions of Drs. B. Pasamanick and F. A. Kruger, Columbus, and M. D. Armstrong, Yellow Springs, are thankfully acknowledged. Our special thanks are due to Dr. S. Dinitz, Columbus, the first subject whose saliva elicited the 'Δ optical density 8-minute' effect, and to Drs. E. C. Kornfeld, R. G. Jones and W. R. Kirtley, from the Eli Lilly and Co., Indianapolis, who courteously supplied us with the imidazole derivatives.

The work was supported by the State of Ohio Department of Mental Hygiene and the U.S. Public Health Service, National Institutes of Health, Division of Mental Health, Grant No. *M*–2731.

Flight by Man-Power

BEING interested in the possibility of flight by man-power, we have read Dr. D. R. Wilkie's communication[1] on the "Work Output of Animals: Flight by Birds and by Man-power".

We agree[2] that for mechanical similarity the power requirement is a function of $(\text{weight})^{1\cdot167}$. Moreover, for flying insects and birds[3] we obtained from Pütter's data a different exponent for this statistical relationship, namely $(\text{weight})^{0\cdot667}$. It is interesting to note that according to the theory of biological similarity[2], the limits for these exponents of body-weight are 1·167 for mechanical similarity, and 0·667 for the electrodynamical similarity, whereas for biological similarities, power is a statistical function of $(\text{weight})^{0\cdot73}$.

Thus, in accordance with the principle of mechanical similarity the power requirement for a flying machine is proportional to $(\text{weight})^{1\cdot167}$; the same relationship was obtained by Nonweiler (quoted in Dr. Wilkie's paper) based on purely aerodynamic considerations. This equivalent conclusion provides evidence that the power necessary to initiate flight exclusively by muscular effort, without additional external forces (potential energy, wind velocity, etc.), is a function of $(\text{weight})^{1\cdot167}$. The slope of this theoretical relationship (line *E* of Fig. 1 in Dr. Wilkie's paper) intersects line *C* of the same graph, which represents the steady-state maximal effort that man is able to perform in oxygen balance for at least 5–30 min.

The theory of biological similarities[2] states that all power functions of living beings are related to $(\text{weight})^{0\cdot73}$, and since it was found[3] that flying insects and birds have mean power requirements which are a statistical function of $(\text{weight})^{0\cdot667}$, we presume that this represents the optimal conditions of natural flight which man should try to achieve during artificial flight.

Furthermore, from the experimental data of Bjerknes and of Müllenhoff, we have calculated[3], by extrapolation from the regression equation based on data for a weight range from the fly to the stork, that a man-powered flying machine (70 kgm. man and 30 kgm. flight-accessories) should have approximately the following characteristics for slow flapping flight: (*a*) flight surface, 6 m.^{2}; (*b*) pressure, 16·8 kgm./m.^{2}; (*c*) speed, 18·2 m./sec.; (*d*) power, 6 kgm.-m./sec.; (*e*) force of the wing-beat, 19·3 kgm.-weight; (*f*) speed of the wing tip, 5·8 m./sec.; (*g*) length of the wing, 3·15 m.; (*h*) wing-beats per second, 0·592/sec.

Another aspect of the same problem is related to the different density of birds and men. In order to have similar flight conditions, it might be wise to construct a man-powered flying machine of approximately the same density of those of insects and birds, so that the aerodynamics of the whole machinery should be similar to the natural models. The transfer of muscular power to the wings and the sensory information of the actual flight conditions must be based on the flight-physiology of insects and birds, since the reflex regulation of flight is of paramount importance.

We agree with Dr. Wilkie in the sense that man-powered flight is possible and should be tested experimentally, because new hypotheses and materials (both metals and plastics) are available which can be used to solve some of the engineering problems involved.

Effect of Nitrate Ion on the Distribution of Sucrose in the Rat's Ventricle

CURRENT work in this laboratory shows that the exposure of driven rat ventricle strips to Locke's solutions, in which all the chloride has been substituted by nitrate, results in an increase of the total sodium in the tissue. In order to determine how this increase was partitioned between the extracellular and the intracellular compartments we attempted to measure the extracellular space by the distribution of sucrose. The results presented below show that this cannot be done in the case of nitrate, and reveal an interesting feature of the action of this anion, which may be that of increasing the permeability of cardiac tissue to a molecular species not ordinarily considered as being able to traverse the cell membrane.

Table 1. WATER CONTENT AND SUCROSE SPACE IN DRIVEN VENTRICLE STRIPS

Perfusion time	Total water content (percentage of wet weight)		Sucrose space (percentage of wet weight)		Sucrose space (percentage of total water)	
	Cl	NO_3	Cl	NO_3	Cl	NO_3
5 min.	(10) 75·56	(7) 77·41	22·23	34·18	29·43	44·14
15 ,,	(10) 75·71	(5) 77·54	27·44	40·03	36·23	51·62
30 ,,	(12) 75·63	(8) 77·18	28·69	48·51	37·91	63·08
1 hr.	(12) 75·31	(6) 77·90	30·88	49·96	41·08	64·11
3 ,,	(4) 75·88	(5) 77·84	34·90	71·12	46·01	91·42
5 ,,	(4) 75·90	(5) 78·25	53·60	76·53	70·61	97·80
7 ,,	(5) 75·42	—	62·14	—	82·38	—
9 ,,	(3) 75·50	—	63·04	—	83·50	—

The preparation of the tissue[1], the composition of the anionically substituted Locke's solution[2], and the experimental procedure[3,4] have all been described previously. In the present experiments the electrically driven ventricle strips were maintained at 37° C. in either chloride- or nitrate-reference solutions for periods up to 9 hr. in the former case and 5 hr. in the latter. Both types of solution contained sucrose in a concentration of 600 mgm./100 ml. The ventricle strips were removed from the muscle baths at the time intervals indicated in Table 1, dried and analysed for sucrose by the method of Ross and Mokotoff[5]. Since nitrate was found to interfere with the colorimetric determination of sucrose it was necessary to eliminate this anion by passing the solution through an anion exchange resin, 'Duolite *A*-101*D*'. Both wet and dry weights were recorded to determine water content.

The results presented in Table 1 show a small but significant increase in the wet weights of the nitrate-treated muscles, amounting to about 2 per cent above those of the chloride controls. Fig. 1 shows the time-course of sucrose distribution in the two classes of muscle. It is evident from Fig. 1 that the time-course of sucrose distribution can be separated, as has been done by Creese[6], into several kinetic components: an early linear phase, 1, an early exponential phase, 2, and a late exponential phase, 3. It is risky, of course, to reify kinetics into anatomical compartments, but it is significant that the early exponential phase becomes asymptotic to a line parallel to the *X*-axis which cuts the *Y*-axis at roughly the value of the extracellular phase[7,8] in the case of chloride. On that basis, the delayed exponential phase may represent either the rate of adsorption of sucrose by some structural barrier or, more probably, its slow penetration into the cell, which can be shown by extrapolation to begin very early in the process of sucrose uptake by the muscle. Treating all the phases, on a first approximation, by means of first-order kinetics, the following values were obtained for the three velocity constants:

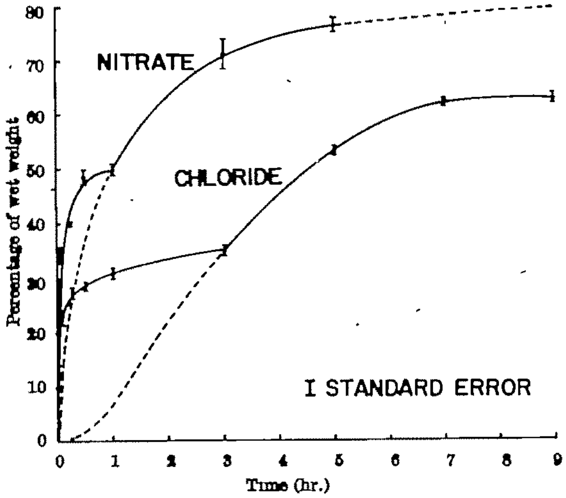

Fig. 1. Effects of NO_3^- and Cl^- on the time-course of sucrose distribution in the driven ventricle

	k_1/min.	k_2/min.	k_3/min.
Cl	0·245	0·0268	0·0046
NO_3	0·662	0·0643	0·0118
NO_3/Cl	2·70	2·25	2·56

Not only is the velocity of the several processes greater in nitrate than in chloride but, in addition, the apparent volume of distribution of sucrose is also increased by this anion, becoming commensurate with that of total tissue water in about 5 hr.

This work was carried out under contract 225(22) between the Office of Naval Research and Stanford University.

An Unidentified Pharmacologically Active Substance extracted from Cerebral Hemispheres

WHILE estimating the 5-hydroxytryptamine content of rat brain, it was observed that the acetone extract stimulated the isolated rat uterus even in the presence of atropine and 2-bromo-lysergic acid diethylamide (*BOL*–148, 10^{-7} gm./ml.). Different parts of the rat brain were then separately extracted and examined, and by far the largest proportion of the active material was found in the cerebral hemispheres. Similar results were obtained when extracts of different areas of other mammalian brains were tested. A study was therefore made of the properties of this smooth-muscle-stimulating substance present in extracts of cerebral hemispheres of mammals.

Smooth-muscle-stimulating substance stimulates the isolated atropinized rat uterus after a latent period of about 45 sec. and continues to increase its tone over the next 5 min. The threshold dose for this effect is, in terms of fresh cerebral hemisphere, about 50 mgm. for the rat and rabbit and about 100 mgm. for the dog. In slightly higher doses, smooth-muscle-stimulating substance also stimulates the isolated atropinized rat fundus, rat colon and rat duodenum. It produces a contraction of the isolated guinea pig ileum in the presence of atropine, mepyramine and *BOL*–148, but the most sensitive preparation used so far is the rabbit duodenum, which is stimulated by an extract of only 20 mgm. of the rat, rabbit or dog cerebral hemisphere. On the blood pressure of the cat or rabbit, smooth-muscle-stimulating substance exerts a depressor response both before and after atropine and mepyramine, yet it is pressor on the blood pressure of the rat. On cardiac and skeletal muscle, it is relatively inactive.

The active material is extracted from cerebral hemispheres with different concentrations of acetone (1–20 vol.) and with trichloracetic acid (2 vol. of 10 per cent) but not with saline containing 0·1 *N* hydrochloric acid. Extracts prepared in this way retain activity for more than 1 month if maintained at 0° C. at neutral or acid *p*H values ; but the activity slowly disappears when the extract is kept at *p*H 11. Smooth-muscle-stimulating substance is not inactivated by incubation with trypsin or chymotrypsin. On paper chromatograms, the active material has an R_F value of 0·60 in a sodium chloride solvent (8 per cent w/v), but it does not move from the origin in solvents of butanol–acetic acid, *iso*propanol–ammonia, or aqueous methanol (60 per cent v/v). With potassium iodate, ninhydrin reagent, Pauly's reagent, Folin–Ciocalteau's phenol reagent, or Ehrlich's reagent, the active material gives no colour reactions characteristic of catechols, amines, amino-acids, compounds containing hydroxyl groups, or indoles.

Thus, smooth-muscle-stimulating substance differs from histamine (which is inactive on the rat uterus), 5-hydroxytryptamine (actions blocked by *BOL*–148), acetylcholine (blocked by atropine), bradykinin (insoluble in acetone)[1], substance *P* (inactivated by chymotrypsin)[2], irin (inactive on rat uterus)[3], γ-aminobutyric acid (inactive on rabbit duodenum)[4], γ-aminobutyryl choline (blocked by atropine)[5], nasal mucosa factor (unstable in acid)[6], and cerebellar factor (which is insoluble in acetone)[7]. It is unlikely to be a polypeptide.

Production of Muscular Weakness in Rats by a Creatine Analogue

IN an effort to clarify the role of abnormal creatine metabolism in producing muscular dystrophy a search for an antimetabolite to creatine has been made. If a specific defect in either the synthesis or utilization of creatine could be produced by an antimetabolite, it would then be possible to assess the change in muscle structure and metabolism which results from impaired creatine metabolism.

One analogue of creatine which has been tested is D,L α-guanidinopropionic acid (alacreatine)[1]. A group of 10 weanling Sprague–Dawley rats of both sexes was fed a purified diet containing 18 per cent casein, 74·4 per cent sucrose, 3 per cent hydrogenated vegetable fat, 2 per cent cod liver oil, and the usual salts and vitamins and supplemented with 2 per cent alacreatine. While receiving this diet during a 6-week period the rats gradually became quite weak in comparison with control animals receiving only the purified diet. The type of weakness seen in the rats receiving alacreatine resembled that seen in rabbits suffering from nutritional muscular dystrophy resulting from vitamin E deficiency. When placed on their side they had difficulty in righting themselves, particularly after exercise.

The finding of severe muscular weakness in animals fed an analogue of creatine strongly suggests that the analogue is a metabolic antagonist to creatine and that the weakness of muscular dystrophy is the result of the abnormal creatine metabolism of that disease. Study of the enzymes of creatine synthesis (transamidinase and guanidoacetate methylpherase) and utilization (creatine kinase) in animals given alacreatine should readily demonstrate a specific defect in creatine metabolism if one is present. This work and experiments to determine the influence of creatine feeding on the syndrome are now in progress.

This investigation was supported by research grant No. *A*-3615, National Institutes of Health.

Damage to Liver induced by DL-Methionine-Ethylester

PERRI *et al.* have observed that tryptophan-methylester inhibits the growth of several bacteria[1]. Horváth *et al.* found that the adaptive enzyme product of *Penicillium chrysogenum* inhibits glycine-, *iso*leucine- and phenylalanine-methylester and supposed that the amino-acid-ester takes part in protein synthesis after the acyl-activation and with its bound carboxyl group stops peptide production[2]. According to this hypothesis the amino-group of the esterified amino-acid is more reactive than the natural one, therefore the activated amino-acid reacts mainly with the ester. Although in the above-mentioned work no completion experiments were performed, the results suggest that the amino-acid-esters behave like antimetabolites on lower organisms.

On the basis of the above we supposed that DL-methionine-ethylester is a methionine antagonist causing liver injury, which then could be inhibited by methionine administration.

Dimethionine-ethylester was synthesized by esterification of DL-methionine and of absolute ethanol in dry hydrochloric acid. The salt of the compound was isolated and recrystallized from absolute ethanol. The dimethionine-ethylester thus produced was chromatographically uniform.

Albino rats of both sexes weighing 80–90 gm. were used in the experiments. They were fed a normal diet during the experimental period and were divided in three groups. 7 rats (Group I) were given 0·34 m.mole methionine ; 16 rats (Group II) 0·24 m.mole dimethionine-ethylester and 7 rats (Group III) 0·34 m.mole methionine + 0·24 m.mole dimethionine-ethylester daily for 17 days, intraperitoneally. The dimethionine-ethylester was always administered after neutralization. Six rats from Group II died spontaneously between the fifth and the seventeenth day; in the other groups no death occurred. On the eighteenth day the rats were killed by decapitation, the liver was immediately removed, weighed and worked up histologically.

All the animals in group II had enlarged livers; in Groups I and III the livers were of normal size (Table 1).

Table 1

Group	No. of rats	Daily intraperitoneal administration in m.mole/rat	Days of administration	Liver-weights in gm./100 gm. body-weight
I	7	0·34 methionine	17	3 94 ±0·42 } t=1 06
II	16	0·24 methionine-ethylester	17	4 5 ±0 41 } P>0 2
III	7	0 34 methionine + 0 24 methionine-ethylester	17	3 62 ±0·45

Histological examination revealed that in Group II only one liver was normal; the others showed parenchymatous degeneration combined with perilobular fatty infiltration of various grades. Among the seven rats of Group III five had normal livers, and two showed mild fatty infiltration (Figs. 1, 2 and 3).

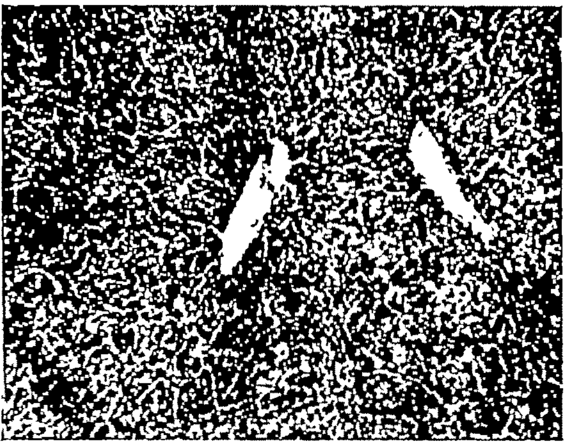

Fig. 1. Liver from group I. Normal structure. Hæmatoxylin-eosin stain. (× 200)

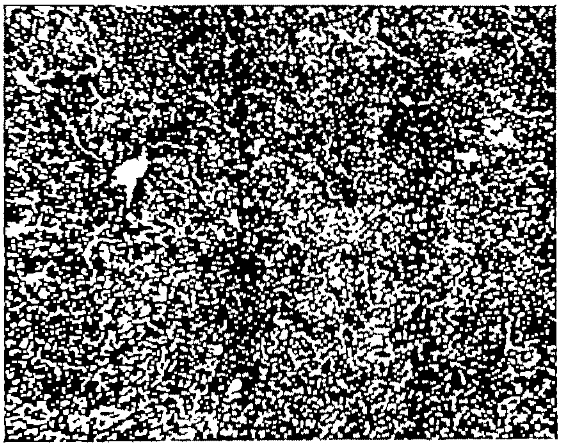

Fig. 2. Liver from group II. Parenchymatous degeneration with severe perilobular fatty infiltration. Hæmatoxylin-eosin stain. (× 200)

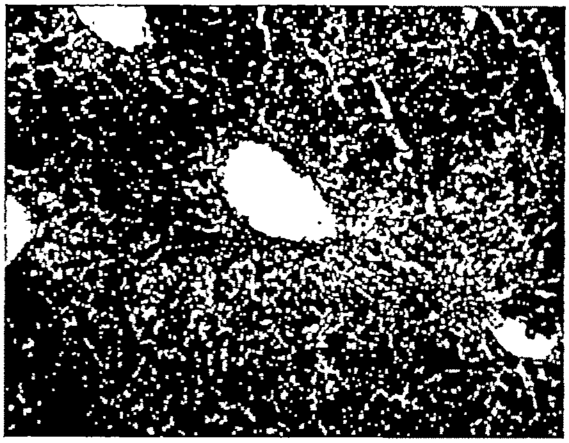

Fig. 3. Liver from group III. Mildly swollen liver baulks. Hæmatoxylin-eosin stain. (× 200)

It is therefore concluded that dimethionine-ethylester induces enlargement and pathological changes in the liver. The enlargement is presumably due to an increase in fat and water contents, while the injury itself depends on the individually different activity of the non-specific esterase. In this way various quantities of dimethionine-ethylester were destroyed, resulting in injury of varying gravity. This assumption, however, will have to be supported by further investigations.

Effect of Some Aromatic Hydroxy Compounds on the Phagocytic Activity of the Reticulo-Endothelial System

It has been reported previously that œstrogens stimulate the reticulo-endothelial macrophages in the spleen, liver and lymph nodes and lead to mobilization of the macrophages into the blood-stream and thus probably to an increase in the general defence of the body against infection and perhaps new growths; and that these results suggested the desirability of finding a substance which possesses a still more powerful stimulating effect on the reticulo-endothelial system without the ill effects of œstrogens[1]. Since then, the effects of various stilbenes, steroids, aliphatic hydrocarbons, antibiotics and sulphonamides on the phagocytic activity of the reticulo-endothelial system have been investigated and reported[2–4]. So far, the strongest stimulants of phagocytic activity are also strongly œstrogenic and it would appear that the configuration of the molecule which confers œstrogenic activity is also essential for reticulo-endothelial stimulation. Many other compounds are therefore being examined in the hope that the results may throw more light on the nature of the stimulative factor.

The present communication is a report on the effect of four aromatic hydroxy compounds on the phagocytic activity of the reticulo-endothelial system.

Thirty male white mice (*T.O.* Swiss strain) of 20–27 gm. body-weight were used in these experiments. Five animals were used to test each substance, each animal receiving one subcutaneous dose of 0·5 mgm. of the compound in 0·05 ml. arachis oil daily for 6 days. On the eighth day the phagocytic activity was measured by the rate of disappearance of a known amount of specially prepared carbon from the circulating blood[7], the procedure used being as follows. Each animal was given one intravenous injection of carbon of particle size 250 Å., the dose of the carbon being calculated on the basis of 16 mgm. per 100 gm. body-weight. Blood was then taken at short intervals during the first 60 min. following the injection, and the concentration of the carbon in each blood sample was measured by an absorptiometer. The logarithmic values of the absorptiometer readings lie along a straight line when plotted against time, and the slope of the line has been taken as the measure of total body phagocytic activity or the phagocytic index, which is denoted in the present communication by the symbol *K*.

Ten of the animals were used as controls and received 0·05 ml. arachis oil once daily for 6 days. The phagocytic activity was then measured on the eighth day by the carbon method referred to above. The arachis oil controls showed a phagocytic index or *K* value of 13 ± 2·4.

Table 1. EFFECT OF SOME AROMATIC HYDROXY COMPOUNDS ON THE PHAGOCYTIC ACTIVITY OF THE RETICULO-ENDOTHELIAL SYSTEM

Compound used	Phagocytic index (*K* value)
Racemic 3 : 4-di-*p*-hydroxyphenylhexan-1 : 6-diol	16 ± 1·6
meso 3 : 4-di-*p*-hydroxyphenylhexan-1 : 6-diol	17 ± 2·6
meso ββ′-di-*p*-hydroxyphenyladipic acid	18 ± 3·3
1 : 2-Di-α-naphthyl-1 : 2-dihydroxyacenaphthene	15 ± 1·8
Arachis oil controls	13 ± 2·4

The results are shown in Table 1. Compared with the control values, it can be seen that the four compounds investigated, which are similar in type, have little or no effect on the phagocytic activity of the reticulo-endothelial system.

We are indebted to Sir Charles Dodds for generously supplying these compounds. We also gratefully acknowledge assistance from the Central Research Fund of the University of London and from the Medical Research Council.

PATHOLOGY

Production of Tumours in *Rattus (Mastomys) natalensis* by Polyoma Virus

Rattus (*Mastomys*) *natalensis*, the multi-mammate mouse, is an African rodent intermediate in size between the rat and the mouse. These animals have been used in microbiological studies because they are highly susceptible to infection by plague bacilli[1], *Schistosoma mansoni*[2], and *Borrelia duttonii*[3]. They have recently been used in cancer research laboratories following Oettle's report of a high incidence of spontaneous adenocarcinoma of the stomach in a *Mastomys* colony in Johannesburg, South Africa[4]. Since the polyoma virus has been shown to produce tumours in mice, Syrian hamsters, rats and rabbits[5], we were interested in determining the response of *Mastomys* to this agent.

A small colony of *Mastomys* is now maintained by Dr. H. L. Stewart and Dr. K. C. Snell in the Laboratory of Pathology of the National Cancer Institute in Bethesda, Maryland. Four pregnant *Mastomys* were obtained from this colony.

The strain of polyoma virus used was isolated originally from a filtrate of an extract of a murine parotid gland tumour, and the details of the derivation of this strain have been reported by Dawe and his associates[6]. The virus has been serially passaged in cultures of milk-adapted murine lymphoma cells (strain *P388D1*)[7], and fifth, tenth and fourteenth tissue culture passage pools were used to inoculate the *Mastomys*. Tissue culture medium composed of 20 per cent autoclaved fatless milk and 80 per cent mixture 199 was used to inoculate control animals.

New-born *Mastomys*, less than 12 hr. old, were inoculated subcutaneously on the back with 0·05–0·10 ml. of virus pool or control tissue culture medium. The size of the litters, type of inocula and number of animals studied at autopsy are presented in Table 1. Six months after inoculation, 24 of the 30 animals that had received virus were dead; however, because of cannibalism, it was not possible to autopsy 7 of these. Tumours were found in 14 of the 17 animals that were autopsied. As shown in Table 2, 13 *Mastomys* had tumours in the kidneys, 4 had tumours in the liver, 2 had tumours in the heart and 2 had tumours in the subcutaneous tissues. None of the animals inoculated with control tissue culture medium has died 6 months after inoculation and no tumours have been observed or palpated in these animals.

The tumours of the kidneys varied on gross examination from small nodules 0·2–0·3 cm. in diameter to masses measuring 3–5 cm. in greatest dimension, and they were frequently multi-focal and bilateral. Histologically, they were composed of ovoid and elongated cells which were sometimes

Table 1. NEW-BORN *Mastomys* INOCULATED WITH POLYOMA VIRUS

3	10	8,000,000 *TCD*50 of 5th *TC* passage	2	0	8
4	7	control fluid	7	0	0

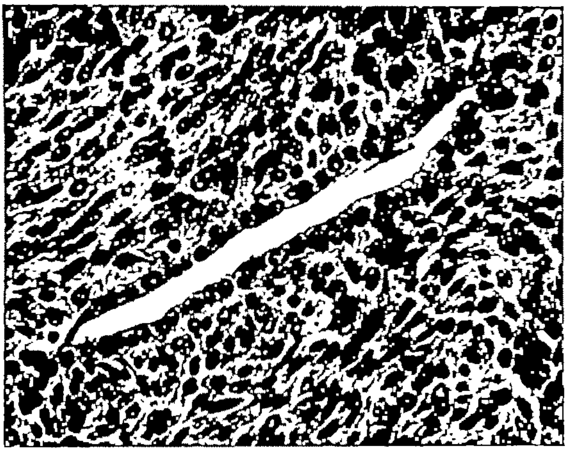

Fig. 1. Renal sarcoma in *Mastomys* inoculated with polyoma virus. A renal tubule is surrounded by tumour cells. Hæmatoxylin and eosin. (× c. 416)

arranged in interlacing bundles, and all were diagnosed as sarcomas. The nuclei of the tumour cells were pleomorphic and hyperchromatic, and frequently there was clumping of chromatin along the nuclear membranes with central clear areas in the nuclei. Similar nuclear changes have been observed in cells of the *P388D1* strain in tissue culture after infection with polyoma virus[7]. Occasionally, the tumours were very vascular and the neoplastic cells were arranged around blood vessels in a manner similar to that described in the intracranial sarcomas produced by polyoma virus in the Syrian hamster[8].

The tumours in the livers of 3 of the animals (Nos. 10, 12, 13, Table 2) were angiomatous in type and similar to those described in the livers of Syrian hamsters inoculated with polyoma virus[8]. The 3 animals with these angiomatous tumours were found dead, and at autopsy they had hæmoperitoneum associated with rupture of vessels of the hepatic tumours.

In the liver of one *Mastomys* (No. 15, Table 2), a white nodule 0·3 centimetre in diameter was noted grossly on the cut surface of the median lobe just beneath the capsule. Histologically, this was composed of irregularly shaped duct-like structures lined by columnar cells with pleomorphic hyperchromatic nuclei and amphophilic cytoplasm. The tumour was not encapsulated, and appeared to invade adjacent liver parenchyma. It was diagnosed as an adenocarcinoma, and we believe that it probably originated from bile duct epithelium, although the possibility of origin from altered hepatic cells has not been eliminated. Tumours of this type have not been described in mice, rats, hamsters or rabbits inoculated with polyoma virus. Proliferation of bile ducts, however, has been described in the livers of *Mastomys* infected with *Schistosoma mansoni*[9]. The relationship of this tumour to the inoculation of polyoma virus is therefore not clear at present.

The two heart tumours were small, each measuring approximately 0·1 cm. in greatest diameter. One was found beneath the endocardium of the right ventricle adjacent to the pulmonic valve, and the other in the wall of the right atrium. Histologically, they were composed of fusiform and oval cells, and resembled the sarcomas found in the hearts of Syrian hamsters inoculated with polyoma virus[8]. The subcutaneous tumours in the *Mastomys* were also diagnosed as sarcomas and were histologically similar to the subcutaneous tumours produced by polyoma virus in Syrian hamsters[8].

It has been possible to isolate polyoma virus in tissue culture from a suspension of one of the renal sarcomas of the *Mastomys*. At the time of autopsy, a portion of the tumour of the kidney from animal No. 11 (Table 2) was frozen at − 20°. It was later thawed and a 20 per cent suspension of tumour tissue was made in tissue culture medium (20 per cent autoclaved fatless milk and 80 per cent mixture No. 199). Cultures of milk-adapted *P388D1* cells were inoculated with 0·25 ml. of the 20 per cent tumour tissue suspension. In one of two inoculated tubes, a cytopathological effect similar to that seen in cultures inoculated with polyoma virus was observed after 21 days. The supernatant fluid from this culture was then inoculated into 9 new-born Syrian hamsters, and all died within 30 days. Five were autopsied and all had multiple tumours similar to those previously described in hamsters inoculated at birth with polyoma virus[8].

Although spontaneous tumours have been described in *Mastomys*, they have rarely been found in animals younger than one year of age, and they differ from the sarcomas of the kidneys and heart, and angiomatous tumours of the liver found in the animals inoculated with polyoma virus[4]. With the possible exception of the adenocarcinoma of the liver in one of our *Mastomys*, it therefore seems unlikely that the tumours we have observed are spontaneous, and we believe that they are related to the inoculation of the polyoma virus. The mechanism by which the virus

Table 2. Tumours in *Mastomys* inoculated with Polyoma Virus

produces tumours, however, remains completely obscure at present.

Since some difference of opinion exists whether to group the *Mastomys* taxonomically with the rat (genus *Rattus* Fischer) or with the mouse (genus *Mus* L.), the response of *Mastomys* to polyoma virus is of interest. The renal sarcomas produced by polyoma virus in *Mastomys* are grossly and histologically similar to tumours produced by polyoma virus in the kidneys of rats and mice[8]. The sarcomas in the heart, however, have not been described in either rats or mice, but are very frequently produced by polyoma virus in the Syrian hamster[9]. Thus far, no parotid gland tumours or thymic tumours similar to those produced by polyoma virus in mice have been found in the *Mastomys*. It should be noted, however, that the virus pools we have used show very little oncogenic activity in mice, although they readily produce tumours in Syrian hamsters.

Additional studies of *Mastomys* inoculated with varying doses and different strains of polyoma virus are now in progress in our laboratory and will be reported in detail later.

Hæmodynamic Aspects of Atherogenesis

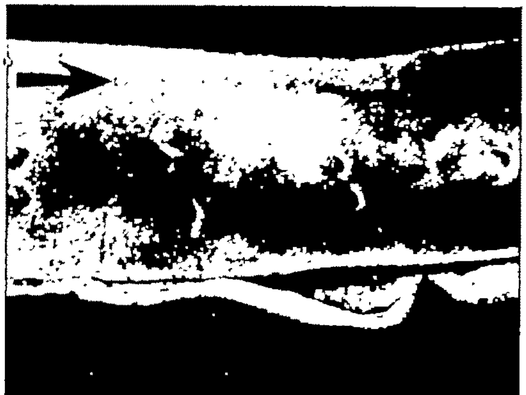
ATHEROSCLEROSIS is generally regarded as a disease process which is mainly due to disorder of metabolic factors such as lipoproteins, hormones, heparin, etc. These factors have been extensively studied, especially with respect to lipoproteins. However, careful examination of the artery at autopsy shows that plaques are scattered all along an arterial branch. An artery of considerable length uniformly and concentrically coated with lipid material without localized regions of sclerosis seems to be quite rare. On the contrary, plaques are in the majority of the cases deposited in a peculiar pattern. Such deposition of lipid materials and the topographical arrangement of plaques cannot be explained readily by general metabolic factors alone. Thus a method of quantitative grading of atherosclerosis has been developed[1] in order to distinguish the role of the general metabolic factors and local factors. This technique has been applied to a study of the interrelationship between cerebral and coronary atherosclerosis[2]. By quantitative grading of sclerosis and systematic analysis of the coronary artery for relative position and severity of plaques one is able to demonstrate the significance of local factors in atherogenesis.

Table 1. EFFECT OF BEND IN AN ARTERY ON ATHEROGENESIS

No. of sections	I/E	Position of sections
135	47·5 ± 14·2*	Pre-bend
125	59·8 ± 11·8	Bend
130	54·9 ± 13·7	Bend
139	48·4 ± 15·4	Post-bend
125	42·7 ± 16·4	Post-bend
105	32·9 ± 14·3	Post-bend

I, Area of intimal material; E, total area of arterial wall; I/E, atherosclerosis units.
* Standard deviation of distribution.

Table 1 shows the effect of the bend in the anterior descending branch of the left coronary artery. Before reaching the bend, sclerosis was measured as 47·5 I/E units; for the bend it was 59·8, 54·9 I/E units; and for the region following the bend, 48·4, 42·7, 32·9 I/E units. The higher value at the bend in the artery shows that this region is more susceptible to deposition.



(1)

(2)

Fig. 1. Early phase of experimental atherosclerosis of rabbit aorta. Note the plaques were beginning to form at each branching point. Flow of blood from left to right, as indicated by arrow. (× 3)

Fig. 2. Advanced phase of experimental atherosclerosis of rabbit aorta. Heavy plaques were formed at each branching point. Note the typical shape of the plaques in advanced sclerosis. Flow of blood from left to right, as indicated by arrow. (× 3)

The plaques along any artery are not randomly distributed as has been reported in the literature. They seem to be located at certain particular sites such as bifurcations. Fig. 1 shows a typical early phase of atherosclerosis which was formed at the branching point of an aorta from a rabbit given cholesterol in its feed. Fig. 2 shows another aorta with a comparatively advanced stage of atherosclerosis. Plaques are also particularly numerous at the branching point of an artery. In both photographs it is evident that plaques are formed at precisely the same location with respect to flow. Theoretical and a full treatment of this particular feature will be published elsewhere.

Anti-neoplastic Activity of Tetrahydro-1,3-oxazine Derivatives

It has been demonstrated that benz-1,3-oxazine derivatives inhibit the growth of Crocker sarcoma in mice[1]. This was partly confirmed by F. Bergel, at the Chester Beatty Research Institute, London (private communication).

Further confirmation of the anti-neoplastic activity of benz-1,3-oxazine derivatives was obtained by the Miyamura test, *in vitro*[2]. Similar results were obtained by Leonardi[3] when he repeated our experiments *in vitro*.

All these results seemed to be sufficiently promising to justify searching for anti-neoplastic substances among the derivatives of 1,3-oxazine. Simpler compounds, derivatives of 5-nitrotetrahydro-1,3-oxazines (I) and 6-methyl-6-phenyltetrahydro-1,3-oxazine (II) proved to be fairly efficient *in vitro*[2].

Their activity against the solid form of Ehrlich ascites carcinoma is shown in Table 1 and solid form of amytal ascites sarcoma in mice in Table 2.

It is believed that the active CH_2 group in position 2 is responsible for the anti-neoplastic activity of 1,3-oxazine derivatives.

Further experiments will be carried out with a number of the compounds (I) to elucidate the influence

BIOLOGY

Fungitoxicity of Metal Ions

The relationship between the toxicity of metal cations and their physico-chemical properties has been considered in terms of electrode potential[1,2], insolubility of the metal sulphide[3], and electronegativity[4]. Danielli and Davies[4] suggested that the toxicity of metal ions is determined by their ability to form un-ionized complexes with ionogenic groupings at the cell surface, and they have taken the electronegativity values of the metals as a measure of the tightness of covalent binding to these groups. The application of this hypothesis to the toxicity of a number of metal salts to fungal conidia[5] has recently been questioned by Miller[6]. In his examination of my experimental results, Miller has arbitrarily disregarded the toxicities of metals less toxic than zinc by terming them "basically not toxic to fungus conidia" although they all possess measurable *ED*50 values. It was, of course, precisely to show that the same toxic mechanism may apply to a wide range of metal ions that these less toxic metals were examined.

Miller also criticizes the standard spore germination technique[7] as a measure of fungitoxicity. This technique determines the fungistatic ability (that is, inhibition of spore germination) of a fungicide as a function of the concentration of the external solution, and is closely related to the practical performance of fungicides. Moreover, the widespread use of this test for many years has established its value as a measure of the relative toxicity of protectant fungicides. Absolute toxicity values will only be obtained when the concentration of toxicant at cell receptor sites can be determined. For some years, McCallan and Miller[8] have advocated the ratio of the weight of fungicide accumulated by the fungal spores at the *ED*50 to the weight of spores as a measure of 'innate' toxicity. Although their ratio of μgm. toxicant/gm. spore weight is a most valuable measure of fungicidal activity and of the uptake of fungicides by spores[9], this weight ratio cannot be regarded as fundamentally related to absolute toxicity until much more information on the mode of action of fungicides and their possible detoxication by the cell is available.

The value of the electronegativity hypothesis may best be shown by an examination of the results of some recent experiments in which the fungitoxicity of twenty-two metal cations to conidia of *Botrytis fabae* Sardiña has been determined. The median effective doses (*ED*50) of unbuffered solutions of nitrates of potassium, sodium, barium (*ED*50 extrapolated), strontium, lithium, calcium, magnesium, manganese, zinc, beryllium, thallium, yttrium, lead, chromium, nickel, cobalt, palladium, copper, and silver, of mercurous and mercuric chloride, and of osmium tetroxide were estimated as before[5]. *B. fabae* conidia gave 98–100 per cent germination after 18 hr. incubation at 25° in distilled water, so that a spore stimulant was not required. In Fig. 1 logarithms of the *ED*50 values of the metal ions are plotted against the electronegativities of the metals as calculated by Pauling[10] and Hałaszinsky[11]. Hałaszinsky calculated electronegativities by Pauling's method for the whole Periodic Table, including values for some of the different valence states of the transition elements. Although electronegativities are not in their nature quantities which can be defined precisely, modern work has largely corroborated Pauling's original values[12].

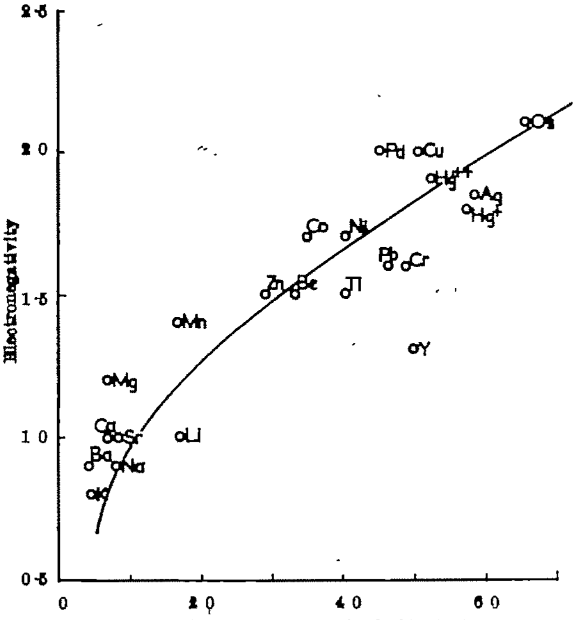

Fig. 1. Graph of toxicity of metal cations to *B. fabae* against electronegativity of the metal

Danielli and Davies[4] have shown that the values of Jones[13] for the toxicities of various cations to the planarian, *Polycelis nigra*, fit an exponential relationship of the form:

$$\log [M^{q+}] = \alpha - \gamma \exp(-0{\cdot}25x^2)$$

where $[M^{q+}]$ is the concentration of the metal cation of valency q in the bulk phase which gives the standard toxicity, x is the difference between the electronegativity of the metal and that of oxygen, and α and γ are constants. From the results in Fig. 1, $\log [M^{q+}]$ was plotted against $\exp(-0{\cdot}25x^2)$ and the regression line calculated, giving $\alpha = 1{\cdot}72$ (S.E., $0{\cdot}59$) and $\gamma = 13{\cdot}98$ (S.E., $1{\cdot}48$). These values of α and γ were used to plot the curve in Fig. 1 which, in spite of the anomalous position of yttrium, may be considered to give a good fit to the experimental results. In view of the very different organism tested and the different electronegativities used, the values of α and γ are in reasonable agreement with those given by Danielli and Davies, namely, 0·95 and 9·28.

These results certainly suggest that there is a common, non-specific, toxic action for most metal cations which can be related to their strength of covalent binding to the surface ionogenic groups (for example, imidazole, carboxyl, phosphate, or sulphydryl) present outside the cell protoplast. It must be pointed out that there is a great deal of evidence from work with bacteria, yeast and fungi to show that the initial uptake of cations is a surface phenomenon[13]. The extent of metal accumulation by fungal spores is too great to assume a classical unimolecular adsorption layer[14], but rather an adsorption in depth on the surface matrix (ref. 13a). Danielli and Davies point out that the formation of an un-ionized complex between metal ion and surface ionic groups may alter membrane permeability; and Miller's results, showing increased uptake by fungal spores after treatment with silver ions or a surface-active agent, can be attributed to reaction between the metal ions and lysed cellular components. This reaction, however, will be secondary to the formation of un-ionized complexes, which is considered to be primarily responsible for the fungistatic action of metal cations.

The experimental work discussed here will be reported in detail elsewhere.

A Method for the Detection of Inhibition of Auxin Transport

EXPERIMENTS in which auxin has been supplied to either the morphologically apical or basal ends of coleoptile sections have been carried out by Åberg and Khalil[1] and by Housley *et al.*[2]. Both investigations demonstrated that more growth occurred when the apex-to-base auxin transport system could operate, that is, when the apical ends were in contact with the auxin. The present communication confirms this result and shows how the method can be used to investigate auxin transport and its inhibition.

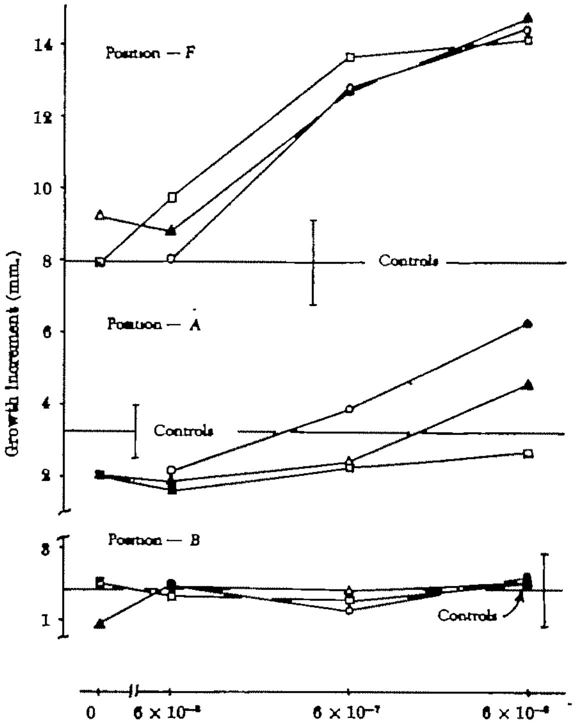

Fig. 1. Interaction of indolyl acetic acid and tri-iodobenzoic acid in growth of coleoptile sections.
Concentration of tri-iodobenzoic acid: ○, nil; △, 2×10^{-7} *M*; □, 2×10^{-6} *M*

Ten 1·0-cm. coleoptile sections cut from standard dark-grown wheat seedlings are supported upright inside a 1 in. × 1 in. vial containing 1·0 ml. of sucrose-buffer solution[3] with or without auxin, and in the presence and absence of a second substance such as 2,3,5-tri-iodobenzoic acid. The sections are placed so that the apical end (*A*-position), or the basal end (*B*-position), of each is just below the surface of the liquid. In addition, in certain experiments, sections are floated on the solutions (*F*-position). No special precautions are taken to guard against surface creep of solution along the sections, or against capillary rise between the coleoptile and the included leaf. Growth increments are measured after 18 hr. in darkness at 25° C. at high humidity.

Sections in the *A*-position consistently show a greater growth response to indolyl acetic acid than sections in the *B*-position. This differential response is still apparent when: (*a*) the portion of leaf is removed, (*b*) the sucrose buffer is omitted from the medium (in which case all responses are lower), (*c*) each of the sections is cut into two 5-mm. portions, and both of these tested in both positions, and (*d*) oat coleoptile sections are used.

Fig. 1 shows results of an experiment on the interaction of indolylacetic acid and 2,3,5-tri-iodobenzoic acid. Points on the graphs represent growth increments found for sections in the *F*, *A* and *B* positions in different combinations of the two substances. Fiducial limits of controls, calculated from 5 sets of 10 sections, are shown.

In the *B*-position, externally applied indolyl acetic acid gives no growth response at the concentrations used. There is no significant difference between controls in the *A* and *B* positions; control growth might therefore be ascribed to the activity of endogenous auxin. In the *A*-position, growth responses to exogenous auxin do occur, although they are less than in floating sections. It is suggested that responses in the *A*-position represent an assay of transported indolyl acetic acid. Where tri-iodobenzoic acid is present, they are reduced or absent. Since these concentrations of tri-iodobenzoic acid do not interfere with growth induced by indolyl acetic acid in the *F*-position, it can be argued that the reduction they cause in *A*-position responses is due to an inhibition of auxin transport, rather than to effects of tri-iodobenzoic acid on auxin uptake and assay. Such effects have been tested and corrected for by other workers[4,5], who have likewise found that tri-iodobenzoic acid inhibits auxin transport. The same argument applies to destruction of auxin induced by tri-iodobenzoic acid, which has been shown to occur[5,6] at concentrations higher than those found here to inhibit transport.

Experiments of this type may prove suitable for the testing of tissue extracts for substances that might regulate some aspects of plant growth through their effects on the transport of auxin. There is direct evidence for the existence of transport-modifying substances[7], and their activity can be postulated as a working hypothesis to account for a variety of correlation phenomena. Substances already available in a pure form can also be examined. For example, the method has shown that colchicine, in concentrations (0·001 and 0·01 per cent) that are within the range causing apolar cell enlargement in root 'c-tumours', does not behave in the same way as tri-iodobenzoic acid.

Maternal Inheritance and Interspecific Hybrids of the Liverwort *Sphaerocarpos*

Sex determination in *Sphaerocarpos*, a genus of dioecious liverworts, is genetically controlled[1]. When the spores of a tetrad derived from a single spore mother cell are germinated, two of the sporelings develop into male and two into female gametophytes. Cytological studies have shown that there are eight chromosomes in the complement of each sex. Of these, seven of the eight chromosomes in the female are similar to seven in the male. The eighth chromosome of the female, the *X* chromosome, is larger than the seven autosomes; the eighth chromosome of the male, the *Y* chromosome, is smaller than the autosomes[2-4].

Of the seven species in the genus, there are no readily apparent morphological differences separating the male plants. Moreover, only one species is easily identified on the basis of the vegetative characteristics of its female plant[4]. Although some vegetative differences are said to exist between the female plants of the other six species, apparently these differences are difficult to ascertain in field populations. Therefore, these species are usually separated on the basis of spore characteristics, that is, the pattern of spore markings and whether or not the four spores remain adherent in a tetrad after meiosis. Recently, in the work reported here, it was found that these spore characteristics are isolated from the effects of hybridization. That is, hybrid spores are not intermediate between the two parents, but closely resemble the maternal species.

Three species of *Sphaerocarpos* were used during the present work: *S. donnellii* Austin (from Florida), *S. drewii* Wigglesworth (from California) and *S. cristatus* Howe (from California). The spores of *S. drewii* and those of the particular race of *S. donnellii* used in this work are adherent in a tetrad; those of *S. cristatus* are separate. Sexual reproduction between these species is normally precluded by geographical isolation. Clonal cultures of each sex, derived from single-spore isolates, were grown separately. Two separate matings involving reciprocal crosses between the three species were attempted. Simultaneous intraspecific matings served as controls and also indicated the number of archegonia with eggs receptive to fertilization at the time of each mating. Between 60 and 105 archegonia contained receptive eggs in each control culture.

Of concern here are only those crosses which resulted in the development of mature sporophytes and thus mature spores. Mature hybrid sporophytes resulted from the following matings: *S. cristatus* ♀ × *S. donnellii* ♂; *S. drewii* ♀ × *S. cristatus* ♂; and *S. donnellii* ♀ × *S. cristatus* ♂. Only in matings of *S. cristatus* ♀ × *S. donnellii* ♂ did the number of sporophytes produced compare to that for the control, *S. cristatus* selfed. Considerably fewer sporophytes resulted from the mating between *S. drewii* ♀ × *S. cristatus* ♂ than from the control, *S. drewii* selfed. The second mating between *S. donnellii* ♀ × *S. cristatus* ♂ resulted in a single sporophyte which produced morphologically normal spore tetrads.

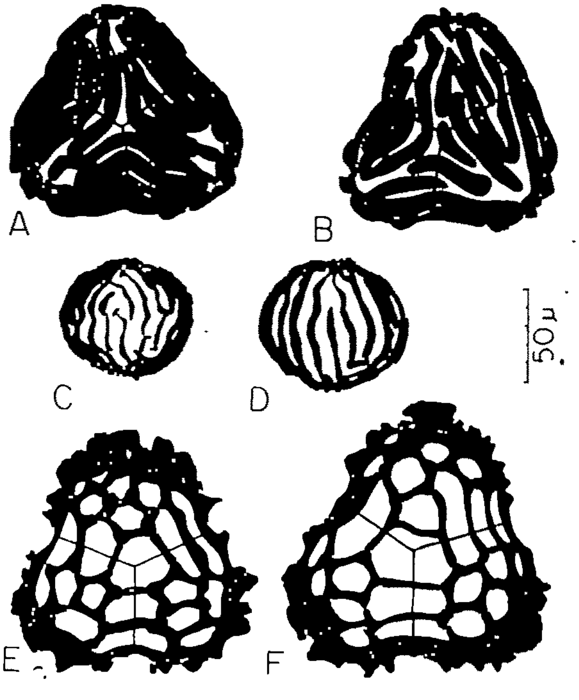

Fig. 1. Spores and spore tetrads of *Sphaerocarpos*. Spores of the maternal species are on the left; those of the hybrids on the right. *A*, *S. drewii*; *B*, *S. drewii* ♀ × *S. cristatus* ♂; *C*, *S. cristatus*; *D*, *S. cristatus* ♀ × *S. donnellii* ♂; *E*, *S. donnellii*; *F*, *S. donnellii* ♀ × *S. cristatus* ♂

Spore characteristics of the parent species and the hybrids are depicted in Fig. 1. All hybrid spores within a single sporophyte and in different sporophytes of the same mating are essentially similar to those shown. It is evident that the hybrid spores have both the general and the definitive characters of the maternal species. Similar results were reported by Allen[5] in the cross between *S. texanus* Austin ♀ × *S. donnellii* ♂. In addition, Allen[6] found that within the species *S. donnellii* the character of adherent versus separate spores followed the line of descent of the *X* chromosome. Although the possibility of cytoplasmic inheritance through the egg cannot be entirely disregarded (see Wettstein[7] for cytoplasmic inheritance in mosses), the most plausible explanation for this pattern of inheritance is that the spore morphology is determined by the genetic composition of the *X* chromosome.

Naturally occurring hybrids have not been found in liverworts[8]. In *Sphaerocarpos* it is clear that naturally occurring hybrids would not be recognized as long as spore characteristics are equated with specific identity. These hybrids would routinely be referred to the maternal species. This means that hybridization will have no taxonomic meaning until species identification includes the use of additional, non-spore characters. It would be of interest to learn how many of the reported differences between the female plants of the species of *Sphaerocarpos* are sex-linked, how many are determined by autosomes and how many are determined by the environment. A critical re-examination of the genus is indicated, utilizing cultures grown under uniform laboratory conditions.

Significance of the Type of Host Plant Crop in Successful Biological Control of Insect Pests

RECENT publications[1-3] on the status of biological control of insect pests have revealed widely divergent opinions on the potentialities of this method of pest suppression. The fact that in the past a high percentage of successful results has occurred in tropical islands led Taylor[1] to conclude that "there is little future for it in continental areas", and to re-emphasize an earlier thesis of Imms[4], to the effect that only such insular conditions are basically suited for this technique. This opinion was rejected by Simmonds[5], whose point of view is supported by Clausen[2,6] on the basis of reviews of work done in North America during the past twenty-five years.

In these and other publications[6-8] bearing on the prerequisites of successful biological control practice, no reference is made to an environmental factor which appears to have been of significance in island and continental experiments. All cases where introductions of natural enemies are reported by competent authorities[9,10] to have given full commercial control of the pests, and the majority of those where control has been partial pertain to perennial crops. More specifically these plants have been sugar-cane, alfalfa, coconut, citrus, coffee and sundry deciduous fruit, forest or shade trees. The following examples may be cited: the sugar-cane weevil *Rhabdoscelus obscurus* (Boisduval) and the leaf-hopper *Perkinsiella saccharicida* Kirkaldy by *Microceromasia sphenophori* (Villeneuve) and *Cyrtorhinus mundulus* (Breddin) in Hawaii; the coconut moth *Levuana iridescens* Bethune-Baker, the scale *Aspidiotus destructor* Signoret, and the leaf-miner *Promecotheca reichei* Baly by *Ptychomyia remota* Aldrich, *Cryptognatha nodiceps* Marshall, and *Pleurotropis parvulus* Ferriere, respectively, in Fiji; the citrus pests *Icerya purchasi* Maskell, and *Pseudococcus gahani* Green by *Rodolia cardinalis* (Mulsant), *Coccophagus gurneyi* Compere and *Tetracnemus pretiosus* Timberlake in California; the citrus blackfly *Aleurocanthus woglumi* Ashby by *Eretmocerus serius* Silvestri in the West Indies and by *Amitus hesperidum* Silvestri and *Prospaltella* spp. in Mexico; the citrus whitefly *Aleurocanthus spiniferus* (Quaintance) by *Prospaltella smithi* Silvestri in Japan; the coffee mealybug *Planococcus kenyae* Le Pelley by *Anagyrus kivuensis* Compere in Kenya; the woolly apple aphid *Eriosoma lanigerum* (Hausmann) by *Aphelinus mali* (Haldeman) and the blue gum scale *Eriococcus coriaceus* Maskell by *Rhizobius ventralis* Erichson in New Zealand; the larch sawfly *Pristophora erichsonii* (Hartig) by *Mesoleius tenthredinis* Morley in Canada; and the eucalyptus snout weevil *Gonipterus scutellatus* Gyllenhall, by *Anaphoidea nitens* Girault in New Zealand, South Africa, Madagascar and Mauritius.

Consideration of these and the many other attempts to utilize biological agents leads to the conclusion that these agents have been particularly effective where the host plants are trees or other perennials maintaining their geographical locations over periods of many years. The case of sugar-cane is somewhat exceptional in that there is frequent cutting to ground-level. But since maturity is reached 10–20 months after planting, crops overlap, and ratooning is common at least under moist tropical conditions, the plants provide an approach to the more stable and permanent conditions in the tree crops. Indeed, some authors[11] have actually suggested that tall canes maintain an environment more in common with a forest than a savannah since many sugar-cane pests appear to have been originally forest inhabitants. Where sugar-cane is grown in marginal climatic areas such as Louisiana and Argentina, the length of the frost-free season is critical and the crop is cut annually. Under these conditions control of pests by natural enemies has not matched that obtained in the tropics.

The special suitability of tree crops as environments for the action of biological agents is seen also in the results of long-term field studies on biological balance in California avocado orchards by Fleschner[12,13]. It is seldom necessary to apply chemical pest control treatment in these orchards; but Fleschner showed by numerous experiments that when entomophagous insects were excluded from trees in any area phytophagous mite and insect populations increased to damaging levels. A further illustration of the great significance of stable environments in control programmes involving living organisms is apparent on examination of experiments in the biological control of weeds by insects. Outstanding successes to date have been against perennial weeds of undisturbed lands[14].

In contrast to pests of tree or other perennial crops, field and garden insects attacking plants such as cereals, maize, crucifers, legumes, etc., have proved to be far more refractory to adequate control by biological agents. So much so that in published lists of pests brought under full commercial control by biological means the omission of examples from these crops is striking. Of course, partial control of a quite valuable nature has been obtained in some field crops, but here again the importance of the perennial plant is evident. The introduction of *Pteromalus puparum* (Linnaeus) and *Angitia* spp. against the cruciferous pests *Pieris rapae* (Linnaeus) and *Plutella maculipennis* (Curtis) in New Zealand ; *Ascogaster quadridentata* Wesmael and *Glypta haesitator* Gravenhorst against pea moth *Laspeyresia nigricana* (Stephens) in British Columbia ; *Euplectrus plathypenae* Howard and *Archytas cirphis* Curran against pasture cutworms *Pseudaletia unipuncta* (Haworth), etc., in Hawaii ; and *Praon palitans* Muesebeck, *Trioxys utilis* Muesebeck and *Aphelinus semiflavus* Howard against spotted alfalfa aphid *Therioaphis maculata* (Buckton) in California[15], are cases in point. Biological control programmes against pests of field and garden crops have often been pursued with a vigour equalling efforts applied to programmes against tree crop pests, as may be seen by the examples cited in Clausen's review of biological control work in the continental United States[5]. The sharp differences in the end-results of these numerous empirically conducted projects during the past seventy years thus suggest a real limitation in the biological control method. Until research shows how such environments may be made more favourable for the action of biological agents, major attention might profitably be directed to pests of perennial crops, where full commercial control is sometimes attainable.

The reasons for these different results are not immediately apparent, although the differences are understandable when the projects are considered from behaviouristic and ecological points of view. The effective environment of an organism has been defined as that containing everything of direct importance to the particular organism. It is probable that tree and other perennial crops provide better approximations to this environment than do field crops because of their fortunate combination of extension, continuity and fixity. These relatively stable and undisturbed conditions year after year must inevitably facilitate sensory reactions of biological agents such as adult entomophagous insects. The overall capacity of an environment to meet the specialized requirements and limitations of these adults may well be a critical, even decisive, factor in the ultimate success of a biological control programme. Really effective natural enemies have been shown to disperse rapidly and have good host-searching capacities. These faculties involve many sense organs, and prevailing opinion is that the adult is attracted first to the type of environment or host area, and then to the host insect[16]. The relative failure of biological control agents against field and garden crop pests suggests the possibility that the organic sensory equipment of the adult entomophagous insect lacks the capacity to cope with the constant disruptions of these plant environments by the cropping and other sequences of present-day agricultural systems. Continuous cultivation under one crop has long been known to favour accumulation of pests, whereas a shifting cultivation or rotation system helps check them. It is to be expected that these same practices create corresponding difficulties in the maintenance or augmentation of the natural enemy populations of the pests. Successful attempts to alter these environments in favour of the biological agents might well follow from an increased knowledge of the factors controlling the orientation and movement patterns of the entomophagous insects and other natural enemies.

Diplodiscus Species Parasitic in the Snail *Paludina vivipara* Lm.

While engaged in researches on larval trematodes in The Netherlands, I collected specimens of the snail *Paludina vivipara* Lm. from a dried-up waterway in the vicinity of Houten (Province of Utrecht). In the course of routine examination, no cercariae having been given off by the snails under laboratory conditions, they were dissected and large numbers of rediae found which proved, by their structure and measurements, to be the larval stage of an amphistome. This is in itself unusual as *P. vivipara* is not recorded as acting as intermediate host for this group of trematodes.

Further dissection and investigation revealed in two of the snails the presence of active trematodes, associated with the tissues of the gut-wall. On investigation, these proved to be adult amphistomes of the genus *Diplodiscus* Diesing 1836, known previously only from vertebrates (Amphibia). Of the members of the genus, the new amphistome most closely resembles *Diplodiscus subclavatus* (Pallas).

The accompanying photograph (Fig. 1) shows the structure and state of development of the amphistome, and its resemblance to *Diplodiscus* sp. is clear. A feature of interest is that only one testis is present, which indicates that the trematodes are in fact adults, young specimens having a double testis which later fuses. The dark paired structure (black in the photograph) is the excretory system.

The measurements of the trematode shown are as follows (in microns) :

Body-length	2,320
Breadth, at *A*	710
Oral sucker	290 × 260
Acetabulum	860 × 610
Testis diameter	300

At present, there appear to be two explanations for the occurrence. One one hand, it is possible that the larval stages of the amphistome have taken place in another mollusc, for example *Planorbis* sp., and that the subsequent eating by *Paludina vivipara* of encysted metacercariae (perhaps by eating a dead

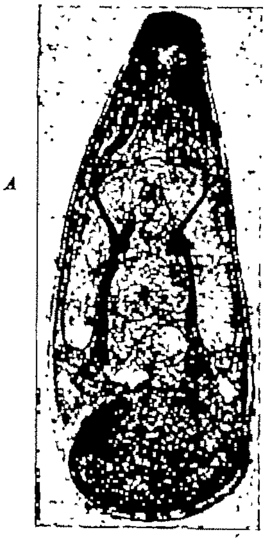

Fig. 1. Measurements given in text

frog or another mollusc) has given the opportunity for full development within a molluscan host, in place of one of the expected vertebrate host (that is, one of the Amphibia).

On the other hand, the presence of amphistome rediæ raises the possibility that the whole of the life-cycle may occur, by means of a type of 'short-circuiting', within the (former) intermediate host, which would account for the lack of free-swimming cercariæ. The cercaria of *Diplodiscus subclavatus*, in contrast, is well known under the name *Cercaria diplocotylea* Fil. Although this has a period of development external to the redia (that is, in the tissues of the snail *Planorbis umbilicatus* L.), it later leaves the intermediate host, and encysts externally.

It is of interest to speculate on the definitive host for this species of *Diplodiscus*, and whether it is a parasite of molluscs, in contrast to all other members of the group, or a parasite of vertebrates that, in exceptional circumstances, has adapted itself to a molluscan host. Whatever the answer to this problem may prove to be, it is the first known case of an amphistome parasitizing an invertebrate.

For the opportunity and facilities to carry out further work on the life-cycle and identification of this trematode, the results of which it is hoped to publish at a later date, I am indebted to the Institute mentioned below and in particular to its director, Prof. D. Swierstra.

Effect of Pyruvate upon Nucleated and Enucleated Fragments of *Amoeba proteus*

THE detection of metabolic differences between nucleated and enucleated fragments of *Amoeba proteus* suffers from the fact that the amounts involved are often minute[1]. In a search for the effect of enucleation upon cellular metabolism, the sensitivity of nucleated and enucleated fragments, respectively, towards selected metabolites may serve as a guide.

The effect of pyruvate on nucleated and enucleated fragments of *Amoeba proteus* was tested as one example. Since enucleated cells are unable to take up food particles, both the controls and the fragments were kept in non-nutrient salt solution without the addition of food particles throughout the experiment. The *Amoebas* were cut into nucleated and enucleated halves with a glass needle. Nucleated fragments as well as whole cells tolerated concentrations of sodium pyruvate up to $2 \cdot 5 \times 10^{-3}$ m*M*/ml. for 24 hr. without appreciable changes either in their mode of movement, or in the morphology of the pseudopodia. However, about 90 per cent of the enucleated fragments were cytolysed within the first 10 hr. of exposure to the same concentration. This difference is the more remarkable since both nucleated and enucleated fragments survive starvation for more than a week.

Since synthesis of protein and ribonucleic acid is dependent on the nucleus, the higher toxicity of the pyruvate for the enucleated fragments might reflect an intracellular increase in lactic acid, caused by a change in the reduced diphosphopyridine nucleotide/diphosphopyridine nucleotide ratio as a result of an insufficient consumption of chemically bound energy[2,3]. It is interesting that a similarly increased sensitivity of enucleated fragments towards 'natural' precursors of proteins and nucleic acids has been found in *Acetabularia*[4].

BACTERIOLOGY

Egg-Yolk Reactions of *Pseudomonas* Species

VARIOUS bacteria are known to produce opalescence in egg-yolk emulsions due to lecithinase or lipase activity. Among these are the lecithinase-producing clostridia and aerobic spore-forming bacilli, and the lipolytic clostridia and staphylococci. Little attention seems to have been paid to the effects produced by Gram-negative organisms growing on egg-yolk media. Felsenfeld[1] showed that the opalescence produced by four strains of *Vibrio comma* and one strain of *Vibrio el tor* was due to lecithinase activity, and Crook[2] made a passing reference to one strain of *Pseudomonas pyocyanea* (*Ps. aeruginosa*) which produced an opalescence on egg-yolk agar. Willis[3] noted the opalescence changes produced by four strains of *Ps. pyocyanea*.

This communication presents briefly the results obtained in a study of the cultural reactions of *Pseudomonas* species on egg-yolk agar and other lecithin and fat-containing media. Thirty strains were examined, of which 15 were strains of *Ps. pyocyanea* isolated from human infections; the remainder consisted of a number of species other than *Ps. pyocyanea*.

All organisms were examined for lipolytic activity by growing them on fat-containing media (tributyrin agar ('Oxoid'), cream agar, monostearate agar and tristearate agar), and for lecithinase activity on egg yolk agar and lecithin agar. Fat-free milk agar was used to determine proteolytic activity, and nutrient agar without other additions was used as a control medium. Some of these media have been described by Willis[3]. In addition, the strains were cultured on phenolphthalein phosphate agar to determine their phosphatase activity, and a note was made of their temperature requirements, pigment production and pathogenicity for mice.

All the strains of *Ps. pyocyanea* produced marked clearing on tributyrin agar in 48 hr., and obvious lipolysis on cream agar, monostearate agar and tristearate agar as indicated by positive results in the copper soap test for lipase[3,4]. Pancreatic lipase (Light and Co.) and four known lipolytic coagulase-positive strains of *Staphylococcus aureus* produced identical results. All strains were proteolytic on milk agar, and, apart from pigment production which varied from strain to strain, they produced no change on nutrient agar. Most strains were phosphatase-positive and were pathogenic for mice.

On the lecithin-containing media—egg-yolk agar and lecithin agar—all strains produced an opalescence and commonly a pearly layer also. On egg-yolk agar the opalescence was almost always confined to the limits of growth; but on lecithin agar it commonly extended away from the edge of the growing colony for some distance into the medium. After treatment with saturated copper sulphate solution the central parts of the opalescence in all cases stained greenish blue, whereas the peripheral parts remained unstained. This was most obvious in the cultures on egg-yolk agar. Pancreatic lipase and the four strains of *Staph. aureus* produced no change on lecithin agar, but produced an intense opalescence on egg-yolk agar and a strongly positive result in the copper soap test on this medium. Pancreatic lipase and the staphylococci also gave positive results in the copper soap test on lecithin agar which had been treated with *Cl. welchii* α-toxin (lecithinase *C*).

Pseudomonas species other than *Ps. pyocyanea* acted variously on the different media. In general, those which grew at 37° C. gave similar results to those outlined for *Ps. pyocyanea*, while those which grew at 25° C. but not at 37° C. were comparatively inactive.

There is no doubt that many of the strains of *Pseudomonas* species examined are lipolytic, and this activity would account for the opalescence produced by them on egg-yolk agar. However, the fact that these organisms produce an opalescence on lecithin agar which stains with copper sulphate solution, whereas lipolytic staphylococci and pancreatic lipase produce no change in the medium, suggests that they produce also a lecithinase *C*. Lipolysis of the diglyceride liberated from the lecithin molecule by attack by lecithinase *C*, as occurs in the case of *Clostridium oedematiens* type *A*[2], provides the simplest explanation of the results obtained.

Further investigations along these lines are at present being carried out and a detailed report will be published elsewhere.

Two Types of Catalase-like Activity in Lactic Acid Bacteria

WHEN heterofermentative lactic acid bacteria were being tested for hydrogen peroxide production, using adaptations of Kneteman's[1] pyrolusite medium and the blood benzidine medium of Kraus, Nickerson, Perry and Walker[2], it was noted that one group showed a positive reaction on both media, and another group produced peroxide on the pyrolusite medium only. Later, it was found that the latter group, but not the former, possessed a strong catalase-like activity when hydrogen peroxide (10 vol.) was added to the cultures grown on blood media; no such reaction was observed when the cultures were grown on blood-free media. Further experiments were carried out with a basal medium (0·5 per cent Evans peptone, 0·5 per cent 'Lab-Lemco', 5·0 per cent yeast autolysate, 0·05 per cent manganese sulphate, 0·05 per cent 'Tween 80', 0·5 per cent potassium citrate, 1·5 per cent agar, and 0·5 per cent glucose, unless otherwise stated, *p*H 6·5 and autoclaved at 15 lb. for 20 min.) to which blood, lysed by the addition of an equal amount of sterile tap water, was added (5 per cent final concentration). This medium, boiled for 15 min. to destroy the blood catalase before pouring into plates, was inoculated by streaking the surface and incubated aerobically at 30° C. for two days. The evolution of bubbles from bacterial cells on the addition of hydrogen peroxide was accepted as an indication of catalase-like activity. Again the cultures were strongly catalase-positive; the medium itself did not decompose peroxide. Catalase-like activity could also be induced by flooding with hæmin (50 μgm. per ml. hæmatin–hydrochloric acid) catalase-negative cultures, grown on the basal medium, and testing after incubation for a further hour.

A selection of lactic acid bacteria was then examined for catalase-like activity on heated-blood agar and on the basal medium, inoculated and incubated as before. Glucose was replaced by arabinose, fructose, or xylose for certain strains which grew feebly with glucose as the energy source. The identity of the heterofermentative lactobacilli, the *casei-plantarum* group of lactobacilli, the leuconostocs, and the pediococci, was determined so far as possible by physiological and morphological tests. The remaining organisms are listed under the names they had when received from the sources indicated in Table 1. The results (Table 1) show that the property of forming a catalase-like system, in the presence of heated blood, is possessed by a number of strains. A few strains of pediococci, however, were weakly catalase-positive on both heated-blood and blood-free media and are not, therefore, recorded in the table as having catalase-like activity only on heated-blood medium. All other strains of lactic acid bacteria examined were either catalase-negative on the heated-blood and on the basal media or developed a catalase-like activity on the heated-blood medium only. A few strains of *Leuconostoc* and *Lactobacillus plantarum*, National Collection of Dairy Organisms (N.C.D.O. 704), were inhibited in the presence of blood. In these cases cultures on the basal medium were flooded with hæmin and tested as described previously. All were catalase-negative.

These results led to further work on the nature of the hæm-requiring catalase-like system. A washed cell suspension of *L. plantarum*, National Collection of Industrial Bacteria (N.C.I.B. 5914), which is

catalase-positive on heated-blood agar, was prepared from an aerobic culture on the basal medium; the cells then showed no catalase activity. Within 5 min. of the addition of hæmin solution (5 μgm. per ml. hæmatin–hydrochloric acid) they developed a strong catalase-like activity. Holding the cells alone in boiling water followed by the addition of hæmin, or boiling the cells 10 min. after the addition of hæmin, resulted in their failure to acquire a catalase-like activity. Cell suspensions of *L. casei* N.C.I.B. 4113, which is catalase-negative on the heated-blood medium, did not become catalase-positive in the presence of hæmin. These findings suggest that certain lactic acid bacteria possess a protein capable of coupling with a hæm compound to form a system which actively splits hydrogen peroxide. This system did not appear to be sensitive to acidity, since a representative selection of strains exhibited a strong catalase-like activity when they were grown aerobically on heated-blood media at an initial pH of 7·0, 5·4 and 4·5. Anaerobic cultural conditions, however, did lessen the peroxide-splitting activity of a few strains of heterofermentative lactic acid bacteria.

As mentioned earlier, some pediococci were weakly catalase-positive on several media. Therefore all the heterofermentative organisms, the *plantarum-casei* group of lactobacilli, the streptococci, and the pediococci, were examined for catalase activity on the basal medium containing 0·05 per cent glucose. Only six slime-forming strains of *Leuconostoc mesenteroides*, and ten of the pediococci showed catalase activity, the leuconostocs being less active than the pediococci. The catalase activity of all six leuconostocs and five of the pediococci decreased as the glucose concentration was increased. This decrease in catalase activity agrees with previous findings for pediococci[3] and *Lactobacillus plantarum*[4]. The presence of heated-blood or hæmin had no effect upon the activity, which suggests that two distinct catalase-like systems occur in the lactic acid bacteria. A study of the effect of initial pH and oxygen, using 0·05 per cent glucose basal medium, revealed that the catalase-like activity of the leuconostocs diminished with lowering of pH and was absent altogether in anaerobically grown cultures, except for one strain which exhibited a very weak activity after being allowed to stand for 1 hr. in contact with the atmosphere before the addition of peroxide. The catalase-like activity of the pediococci was just as apparent in cells grown aerobically or anaerobically; it was influenced by pH but not uniformly in all strains. The strains showing activity in 0·5 per cent glucose media were only slightly affected by a pH (initial) as low as 4·5. Other strains, catalase-negative in 0·5 per cent glucose media, were as sensitive as the leuconostocs to pH.

There appears, therefore, to be at least two recognizable forms of catalase-like activity in the series of lactic acid bacteria examined. The first is a vigorous hydrogen-peroxide destroying system, not sensitive to acid and requiring an external source of hæm. It is possessed by certain strains of homo- and heterofermentative lactobacilli, pediococci, and leuconostocs. The second is a much weaker, often acid-sensitive system, possessed by further strains of leuconostocs and pediococci. A catalase-like activity similar to the latter type has been recorded previously for the pediococci[3], strains of *L. plantarum*[4], and possibly, though no details were given[5], for non-slime and slime-forming strains of *Leuconostoc mesenteroides*, and additional strains of *L. plantarum*.

This, and further work, will be reported in more detail elsewhere. I wish to express my thanks to Dr. T. Gibson for his advice during this work, to Dr. R. M. Keddie for his criticism, and to those who kindly sent me cultures.

Production of Tuberculin Sensitivity

Delayed, or tuberculin-type, sensitivity occurs in the course of many bacterial infections. It is characterized by skin reactions appearing with 24–48 hr. after intracutaneous injections of bacteria or their soluble products. Like immunological reactions, delayed skin reactions are highly specific, but the products eliciting the reactions need not be antigenic *per se*. Circulating antibodies have not been demonstrated to play a part. Delayed sensitivity is not transferable passively by serum, but can be transferred with the cells of sensitized organisms.

† This test was performed on a different set of animals immunized in exactly the same way. — indicates that the test was negative.

Delayed sensitivity to tuberculin occurs regularly after infection with virulent or attenuated tubercle bacilli as well as after the injection of killed mycobacteria. It can also be produced by injecting native tuberculo-protein along with certain wax fractions of tubercle bacilli[1].

Delayed sensitivity seems to occur mainly when the antigenic materials have been phagocytosed (as is the case in bacterial infections) and there appears to exist a certain correlation between the intracellular state of micro-organisms and their ability to cause delayed sensitivity. An attempt was therefore made to sensitize animals with tuberculin by binding it firmly to phagocytes and using these treated cells to sensitize animals. For these experiments, a purified protein derivative of tuberculin, batch *RT 23* (Statens Seruminstitut, Copenhagen, Denmark), was chosen. This preparation is widely used for tuberculin testing of humans.

A typical experiment is described. Normal guinea pigs were injected intraperitoneally with 10 ml. of a 0·0001 per cent solution of glycogen in saline. Four days later, the exudates consisting mainly of monocytes were collected from the peritoneal cavities. The cells were washed with heparinized Tyrode solution and resuspended in Tyrode. The average yield was about 1 × 10^8 cells per guinea pig. 10 ml. of pooled exudates from 4–6 animals were incubated with 10 mgm. purified protein derivative of tuberculin for 40 min. at 37° C. The cells were then washed five times in Tyrode to remove all non-adsorbed derivative. Studies with the purified protein derivative of tuberculin labelled with chromium-51 (ref. 2) showed that 10^8 cells adsorbed about 0·1 mgm. of the derivative. The washed, sensitized cells were suspended in Tyrode, and new guinea pigs, weighing about 350 gm., were injected into the footpads with approximately 10^8 cells in 1·0 ml. Tyrode.

Twelve days later the guinea pigs were tested intracutaneously with 250 T.U. purified protein derivative of tuberculin. Reactions were read at 4–5, 24 and 48 hr. Table 1 shows the results. The majority of the reactions had all the characteristics of tuberculin reactions. They were indistinguishable in their appearance from the reactions observed in control guinea pigs which had been sensitized at the same time with living *BCG*.

Two guinea pigs (Nos. 2 and 5) had reactions which seemed to be mixed Arthus and tuberculin reactions, appearing earlier but persisting as long as the pure delayed reactions. In another, similar experiment 31 days were permitted to elapse between sensitization and tuberculin testing. The guinea pigs, there too, showed typical delayed reactions.

Similar skin reactions were observed when guinea pigs were tuberculin tested 12 days after they had been injected with purified protein derivative of tuberculin (0·1 mgm. in 0·1 ml. saline) into the centre of a sterile abscess produced four days previously by an intramuscular injection of 0·1 ml. turpentine into the thigh. However, tuberculin sensitivity failed to occur when normal guinea pigs were injected with the derivative directly into the footpads, or into the skin or, intraperitoneally, into preformed four-day-old exudates. Injection of the derivative adsorbed to guinea pig cells from one day-old polymorphonuclear exudates gave irregular results. Four-day exudate cells from rabbits, or red blood cells from guinea pigs, sheep or rabbits, when sensitized with the derivative and injected into guinea pigs, failed to induce delayed reactions. In those instances where no delayed reactions occurred, the guinea pigs developed immediate-type Arthus reactions. Intense local bluing was observed in these animals when they were injected intravenously with Evans blue ½ hr. before skin testing. This reaction is characteristic of active cutaneous anaphylaxis[3]. The presence of antibodies to the derivative in some of these guinea pigs could be detected by passive cutaneous anaphylaxis as described by Ovary[3]. Antibodies appeared more frequently after repeated skin testing with 250 T.U. purified protein derivative of tuberculin.

Animals with characteristic tuberculin reactions did not show active cutaneous anaphylaxis. Circulating antibodies could not be detected and tests for passive cutaneous anaphylaxis were negative.

Histologically, the reactions showed the characteristic features of delayed reactions, that is, infiltration with mononuclear cells, oedema, absence of perivascular infiltrations, few polymorphonuclear leucocytes.

The absorption of soluble antigens to autologous or homologous cells might provide useful experimental models for the study of delayed sensitivity. A variety of systems with different purified protein preparations is currently being investigated.

This work is supported by research grant No. *E*-2104 from the National Institutes of Allergy and Infectious Diseases. We are grateful to Dr. S. V. Boyden for helpful discussions.

SOIL SCIENCE

Potassium-supplying Power of Some British Soils

British soils containing similar amounts of total potassium can vary greatly in their ability to release non-exchangeable potassium, but the reasons for this are not well understood. The non-exchangeable potassium reserves in many soils become available to plants as the exchangeable and water-soluble potassium is removed. Some soils can provide amounts of potassium adequate for crop growth during many years, but the release from reserves in others is too slow to meet crop requirements. The nature of the potassium-containing minerals and their amount and distribution of particle size are undoubtedly important; the past cropping history and the nature and amount of potassium fertilizer residues also influence the release of potassium from soils.

Continuous cropping without potassium fertilizer was used successfully in glasshouse experiments to measure releases of non-exchangeable potassium[1]; the total amount released is termed here the potassium-supplying power of the soil. For 19 different arable top soils, releases of non-exchangeable potassium to perennial ryegrass during 18 months in the glasshouse ranged from none to the equivalent of 2,000 lb. potassium per acre (Arnold, P. W., and Close, B., unpublished results). The soils, all of which contained more than 1·0 per cent total potassium, are divided in Table 1 into poor, moderate and good releasers (< 200, 200–1,000 and > 1,000 lb. potassium per acre, respectively) of non-exchangeable potassium. Only soil 19 is known to have received heavy potassium fertilization. Soils of poor and moderate potassium-supplying power were exhausted before the end of 18 months in the glasshouse, whereas the good releasers continued to provide potassium satisfactorily for grass. The clay (particles < 2μ) obtained from uncropped soils after treatment with hydrogen peroxide and dispersion in sodium hexametaphosphate was divided into parts: < 0·1, 0·1–0·3 and 0·3–2·0μ separates with a Sharples supercentrifuge. The oven-dry weights (104° C.) and the total potassium contents (hydrogen fluoride–sulphuric acid digestion, *EEL* flame photometer) of each clay separate were determined.

The potassium contents of the < 0·1μ separates and their proportions in the soils, plotted in Fig. 1, show that 17 of the 19 soils fall clearly into three categories corresponding to poor, moderate and good rates of release of potassium. High percentages of potassium in the fine clay and/or large proportions of fine clay were associated with large releases of potassium. Two soils were atypical. Soil 16, overlying glauconitic Malmstone, released considerable amounts of potassium to H-resin from silt-size particles[2]. No. 19 is a soil heavily fertilized with potassium from the Broadbalk wheat field (Plot 13); the accumulated fertilizer residues have changed the soil from a poor source of potassium, typified by soil 7 (Broadbalk Plot 11, cropped without potassium fertilizer), to a good source without increasing the potassium content of the fine clay by more than 0·2 per cent. These facts account for the good potassium-supplying powers of the two soils not being reflected in the analysis of their fine clay separates. Results for the 0·1–0·3μ clay separates were almost equally satisfactory for grouping the soils into poor, moderate and good release categories. Again, soils 16 and 19 were atypical. The potassium contents of the 0·3–2·0μ separates and their proportions in the soils, plotted in Fig. 2, showed a less well-defined relationship with the potassium-supplying power of the soils.

Table 1. Soils of Poor, Moderate and Good Potassium-supplying Power

No.	Soil series	Clay < 2μ per cent	Substratum

19	Batcombe (potassium-fertilized annually)	21	Clay-with-flints	

Soil 7: Broadbalk, Plot 11, no potassium.
Soil 9: Saxmundham long-term experiment, Plot 4, no potassium.
Soil 19: Broadbalk, Plot 13, fertilized with potassium.

Because low potassium in the fine clay (< 0·3μ approximately) and small contents of fine clay were associated with poor releasers, fine clay particles are usually more important than coarse clay in releasing potassium in these soils. Fine distinctions between soils cannot, however, be expected, nor can it be assumed that in good releasers the coarse clay is unimportant. A detailed study of soil 9 before and after continuous cropping showed that about 40 per cent of the potassium released came from the

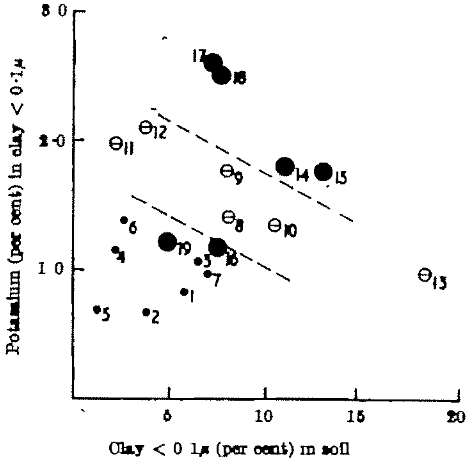

Fig. 1. Percentage and potassium content of clay < 0·1μ in relation to the potassium-supplying power of soils: •, poor; ϴ, moderate: ●, good

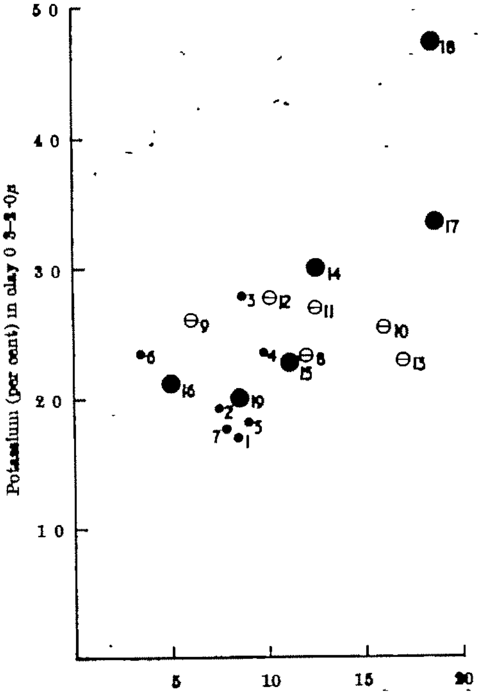

Fig. 2. Percentage and potassium content of clay 0·3–2·0μ in relation to the potassium-supplying power of soils: •, poor; Θ, moderate; ●, good

< 0·1μ clay and 40 per cent from the 0·1–0·3μ clay, there being approximately 7 per cent of each fraction in the soil. The remaining 20 per cent was released from > 0·3μ particles which contained 75 per cent of the total potassium in the soil.

Rouse and Bertramson[3] obtained a positive correlation between the area under the 'illite' peak on X-ray spectrograms of the fine clay separates (< 0·2 and 0·2–1·0μ) and the potassium-supplying power, assessed by chemical means, of several Indiana soils. In general, however, there have been few successful attempts to relate the mineralogical composition of soils to their ability to release potassium. This is not unexpected because, as Reitemeier[4] has stated, even for the most important group of potassium-containing soil minerals, the micas and hydrous micas, their behaviour in soils is little known.

Progress in this subject needs appropriate mineralogical studies in association with simple chemical work designed to reveal trends in soil behaviour, and equally important, to recognize soils that are atypical. Without adequate physical and chemical work, mineralogical studies are likely to be unnecessarily complex, particularly on soils of diverse origin and variable age.

Thanks are due to members of the staff of the Soil Survey of England and Wales, who provided most of the soils used in the work.

STATISTICS

Analysis of Small Experiments

CONSIDERATIONS set out below suggest that unless we can justify certain assumptions, quantitative inferences based on the results of single small experiments may be misleading. Workers who claim they are only interested in clear-cut effects should consider carefully what they mean by this before the experiment starts. There is a danger that if a test gives a statistically significant result this will be regarded *a posteriori*, even if not *a priori*, as establishing an important effect.

Despite certain criticisms made here, small experiments have an undoubted use for suggesting further lines of research. It is also true that a series of small experiments may be more informative than one large experiment.

Significance tests and estimation procedures are commonly based on normal distribution theory, and departures from assumptions will often have more effect in small experiments than in large ones.

We consider this matter in relation to three logically distinct practical situations of common occurrence.

Situation 1. The size of the experiment is limited by the number of experimental units available. Unless we have knowledge gained from previous experience with similar material there is insufficient information in this case to postulate a particular parent distribution. Distribution free randomization tests as developed by Pitman[1] and others are appropriate, but in very small experiments they do not provide tests at a practically useful level. For example, with three replicates of each of two treatments, tests for differences between means can only be performed at certain discrete values exceeding the 10 per cent significance-level. For larger experiments this difficulty does not arise.

Situation 2. Ample potential units are available, but other factors limit the size of the experiment; the units actually used are selected on some criterion of uniformity. Normal distribution theory tests can then be justified if selection is based on standardization of a quantity about which the experimental variate is known to be normally distributed; but it is seldom that such precise knowledge is available. However, selection for uniformity usually invalidates normal distribution theory tests. If we select about average material we may obtain something like a sample from a rectangular distribution, while selection of the best available material will often lead to an upper tail sample not unlike one from an exponential distribution. Incidentally, with selection for uniformity observations need to be taken with a very high degree of accuracy, or the clustering together of values may give rise to large rounding off errors in variance estimates.

Situation 3. Ample potential units are available, other factors once more limiting the size of the experiment; the units actually used are selected at random. Normal distribution theory procedures are correct in this situation providing the variate has an approximately normal distribution over all potential units, but we can expect large standard errors. For other parent distributions sampling theory based on those distributions can be used; but this is seldom done in practice, either because of difficulty in specifying the parent distribution, or on account of complexities in the sampling theory of all but a few distributions.

As alternatives to normal distribution theory tests are not readily available in practice, it is of interest to know something of the effects of using them when they are not theoretically justifiable. I have carried out a series of sampling trials simulating the various situations above for an experiment with three replicates of each of two treatments, there being zero treatment difference. A normal distribution theory t-test was used to detect significant differences, and too high a proportion of significant results was nearly always obtained at both the 1 per cent and 5 per cent levels when normal distribution theory assumptions did not hold. Twelve batteries, each of 200 or more tests, were performed. In only one case, corresponding to random sampling from an exponential distribution, were too few significant results obtained. When testing at the 5 per cent level the proportion of significant results was as high as 10 per cent in one battery. With another battery the proportion of results significant at the 1 per cent level was as high as 5·7 per cent. The last two cases involved samples corresponding to situations 1 and 2, respectively. When normal distribution theory assumptions held, the proportion of significant results was generally close to the test-level, for example, between 5 and 6·7 per cent when testing at the 5 per cent level.

When the alternatives to a small experiment are no experiment or a long wait, it seems clear that a decision on the course of action should not be divorced from statistical considerations associated with the logical situation. The situations discussed are not exhaustive, but cover a wide range of practical cases.

The points raised apply both to estimation and significance testing, and some of them are worthy of consideration in correlation and regression problems with few pairs of observations.

My thanks are due to Dr. S. C. Pearce for stimulating discussions on the logical status of small experiments.

Significance of the Difference between Two Means when the Population Variances may be Unequal

THE purpose of this communication is to present a simple test applicable at the 5 per cent level to the general case of the significance of the difference between two means. If we have two samples of n_1 and n_2 variates from normal populations with the same, though unknown, scale factor, that is, $\sigma_1 = \sigma_2$, the significance of the difference between the means can be tested by the criterion:

$$t = (\bar{x}_1 - \bar{x}_2) \Big/ \sqrt{\left\{ \frac{\Sigma_1 + \Sigma_2}{n_1 + n_2 - 2} \left(\frac{1}{n_1} + \frac{1}{n_2} \right) \right\}}$$

where Σ_1 and Σ_2 represent the sums of squares from the respective means and t is referred to Student's integral with $n_1 + n_2 - 2$ degrees of freedom. If the scale factors are unequal the use of this criterion involves a bias[1] which is small if $n_1 = n_2$ but which can be large if $n_1 \neq n_2$. When the relative scale factor of the two populations is known, appropriate weighting of the sums of squares gives an exact solution. In the case where the relative scale factor is unknown, Fisher[2,3] advocates the use of a different criterion, Behrens' d[4], which can be expressed as:

$$d = (\bar{x}_1 - \bar{x}_2) \Big/ \sqrt{\left\{ \frac{\Sigma_1}{n_1(n_1 - 1)} + \frac{\Sigma_2}{n_2(n_2 - 1)} \right\}}$$

and tables[5,6] are available for the 5 per cent and 1 per cent points of this distribution for a lattice of values of n_1 and n_2 both greater than 6.

In a previous communication[7] it was pointed out that when Student's t is standardized by dividing it by its own standard deviation, the variability of the tails with the number of degrees of freedom is greatly reduced and in particular the 5 per cent values of standardized t, denoted t_s, for 4 or more degrees of freedom all lie within the limits 1·96 and 2·0. With reference to the present problem:

$$t_s = (\bar{x}_1 - \bar{x}_2) \Big/ \sqrt{\left\{ \frac{\Sigma_1 + \Sigma_2}{n_1 + n_2 - 4} \left(\frac{1}{n_1} + \frac{1}{n_2} \right) \right\}}$$

Behrens' d can be adjusted in a similar way giving:

$$d_s = (\bar{x}_1 - \bar{x}_2) \Big/ \sqrt{\left\{ \frac{\Sigma_1}{n_1(n_1 - 3)} + \frac{\Sigma_2}{n_2(n_2 - 3)} \right\}}$$

From the relationship between Behrens' d and its adjusted value d_s, implicit in the above formulæ, the value of d_s corresponding to each value of d in the 5 per cent table was calculated with the remarkable result that all these values of d_s lie within the range 1·96 to 2·0 whereas d itself ranges from 1·960 to 2·447. Hence, provided that n_1 and n_2 are both greater than 6, if $d_s > 2$ the difference between the means is significant at the 5 per cent level; if $d_s < 1·96$, the difference is not significant. The formula was suggested by Welch but he did not give numerical values.

When $n_1 = n_2 = n$, say, the formulæ for t and d are identical but the numerical values for a given level of significance are different; d is more stringent. The corresponding adjusted criteria are:

$$t_s = (\bar{x}_1 - \bar{x}_2) \Big/ \sqrt{\left\{ \frac{\Sigma_1 + \Sigma_2}{n(n - 2)} \right\}}$$

and

$$d_s = (\bar{x}_1 - \bar{x}_2) \Big/ \sqrt{\left\{ \frac{\Sigma_1 + \Sigma_2}{n(n - 3)} \right\}}$$

Both lie between 1·96 and 2·0 at the 5 per cent point for $n > 6$. The factor $n - 3$ compared with $n - 2$ reflects the absence of information about the relative scale factors of the two populations.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT (honours graduate) IN THE DEPARTMENT OF BOTANY—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (August 5).

ASSISTANT LECTURER IN PURE MATHEMATICS—The Registrar, The University, Sheffield (August 6).

UNESTABLISHED ASSISTANT EXPERIMENTAL OFFICER (with a degree in agriculture or pure science with main subject zoology) IN THE DEPARTMENT OF AGRICULTURE AND FISHERIES FOR SCOTLAND, PERTH—The Ministry of Labour, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting G265/OA (August 6).

RESEARCH ASSISTANTS (3) IN THE DEPARTMENT OF METALLURGY, County Technical College, Wednesbury, to work on one of a variety of research projects, several of these being within the field of atomic energy—The Director of Education (Staffing), County Education Offices, Stafford (August 9).

ASSISTANT (with special interest in pig husbandry) IN ANIMAL HUSBANDRY—The Secretary, The University, Aberdeen (August 12).

RESEARCH STUDENTS (with a good honours degree in chemistry or biochemistry) IN THE BIOCHEMISTRY DIVISION OF THE PHYSIOLOGY DEPARTMENT, for investigation on the chemistry and biochemistry of lipids, leading to a M.Sc. or Ph.D.—Dr. C. Long, Biochemistry Division, Physiology Department, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2 (August 13).

TEMPORARY ASSISTANT LECTURER IN PURE MATHEMATICS—The Registrar, University College, Singleton Park, Swansea (August 13).

LECTURER IN THE DEPARTMENT OF METALLURGY for duties primarily concerned with teaching and research in diffraction metallography with particular reference to X-ray work—The Registrar, The University, Liverpool, quoting Ref. CV/T (August 15).

LECTURER OR ASSISTANT LECTURER IN ZOOLOGY with special reference to vertebrate zoology or genetics, at the University of Malaya (Singapore Division)—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 15).

LECTURERS or ASSISTANT LECTURERS (3) IN THE DEPARTMENT OF GEOGRAPHY, University of Malaya, Kuala Lumpur—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Kuala Lumpur and London, August 15).

LIBRARIAN (man or woman graduate with a library qualification and preferably a scientific background)—The Secretary, Royal Veterinary College (University of London), Royal College Street, London, N.W.1 (August 15)

NEUROPHYSIOLOGIST (with Ph.D. or equivalent) IN THE DEPARTMENT OF ZOOLOGY for research on central nervous physiology of the Lepidoptera—The Secretary, University College, Gower Street, London, W.C.1 (August 15).

LECTURER OR VISITING LECTURER IN GEOGRAPHY at the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, August 19).

FOUNDATION CHAIR OF PHILOSOPHY in Monash University, Clayton, Victoria, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, August 22).

JUNIOR LECTURER IN ZOOLOGY—The Registrar, Trinity College, Dublin (August 22).

SENIOR LECTURER IN CROP HUSBANDRY—The Principal, Seale-Hayne Agricultural College, Newton Abbot, Devon (August 22).

ASSISTANT LECTURER IN CHEMICAL PATHOLOGY—The Dean, St. Thomas's Hospital Medical School, London, S.E.1 (August 26).

SENIOR LECTURER, and a LECTURER IN SOIL SCIENCE at the University College of Ghana—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 30).

KEEPER (graduate) OF THE SCIENCE BOOKS in the University Library—The Librarian, Durham University Library, Palace Green, Durham (September 3).

LECTURER IN THE DEPARTMENT OF GEOLOGY—The Secretary, The University, Aberdeen (September 3).

ASSOCIATE PROFESSOR (with special interests in ballistics) IN THE DEPARTMENT OF MATHEMATICS; an ASSOCIATE PROFESSOR (with special interests in applied mechanics, including fluid dynamics) IN THE DEPARTMENT OF CIVIL AND MECHANICAL ENGINEERING; and an ASSOCIATE PROFESSOR (with special interests in applied thermodynamics) IN THE DEPARTMENT OF CIVIL AND MECHANICAL ENGINEERING, Royal Military College of Science, Shrivenham—Civil Service Commission, 17 North Audley Street, London, W.1, quoting Ref. 8/5156/60 (September 5).

LECTURER IN PSYCHOLOGY at the University of Tasmania—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 7).

LECTURER or SENIOR LECTURER IN FLUID DYNAMICS at the University of Tasmania—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 7).

LECTURER/SENIOR LECTURER (preferably with experience in medical bacteriology) IN BACTERIOLOGY at the University of Sydney—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 9).

UNIVERSITY LIBRARIAN (university graduate with appropriate professional experience)—The Registrar, The University, Liverpool (September 10).

SENIOR LECTURER (with a degree in dairying or a degree in pure science or agriculture with a diploma in dairying or in dairy technology) IN DAIRYING—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (September 14).

LECTURER/SENIOR LECTURER (qualified in grassland management) IN ANIMAL HUSBANDRY at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 15).

SENIOR LECTURER and a LECTURER (with an honours degree, preferably in chemical engineering, with research and/or industrial experience) IN CHEMICAL ENGINEERING at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 15).

SENIOR LECTURER IN CLINICAL BIOCHEMISTRY at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 30).

CHAIR OF CHEMISTRY at the School of Pharmacy—The Academic Registrar, University of London, Senate House, London, W.C.1 (October 14).

AGRICULTURAL OFFICER (Tobacco Research) (with an honours degree in natural science (botany), or a degree in horticulture, with suitable postgraduate training or experience), in Nyasaland for experimental work on tobacco including agronomy trials and plant breeding—The Director of Recruitment, Colonial Office, London, S.W.1, quoting Ref. BCD.63/4/04/T.

AGRONOMIST (Livestock), (with a good honours degree in agriculture and postgraduate experience or training in animal genetics) in Uganda, to take charge of a large breeding scheme designed to produce improved beef cattle utilizing local and imported stock—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/9/038.

ASSISTANT LECTURER or LECTURER (with qualifications in zoology with biochemistry or physiology)—The Principal, Derby Training College, Uttoxeter New Road, Derby.

CENTRAL ELECTRICITY BOARD RESEARCH FELLOW (with a good degree in electrical engineering or physics of a British university or an equivalent qualification, and preferably experience of vacuum electronics) IN THE DEPARTMENT OF ELECTRICAL ENGINEERING for work on thermo-electron engines—The Secretary, University College, Gower Street, London, W.C.1.

LECTURER IN TROPICAL HYGIENE—The Dean, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1.

LECTURER or ASSISTANT LECTURER IN MATHEMATICS at Makerere College (University College of East Africa)—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1.

LECTURER (with an honours degree in chemical engineering or Corporate Member of the Institute of Chemical Engineers) IN CHEMICAL ENGINEERING—The Registrar, The University, Nottingham.

LECTURERS (2) IN ZOOLOGY, one to teach histology and microtechnique, and the other to teach ornithology (and if possible animal behaviour)—McGill University, Montreal, Quebec, Canada.

PROFESSOR or ASSOCIATE PROFESSOR (male graduate of a British university with appropriate teaching experience) OF BIOLOGY at Nanyang University, Singapore—The Director, Recruitment Department, British Council, 65 Davies Street, London, W.1, quoting Ref. N.11 T(60).

SENIOR DEMONSTRATOR IN THE DEPARTMENT OF PHYSICS—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1.

EDUCATIONAL CO-OPERATION IN THE COMMONWEALTH

THE Commonwealth Teachers Bill, which received a second reading in the House of Commons on May 17 and the Royal Assent on June 2, gives effect to the second of the undertakings given by the United Kingdom Government at the Commonwealth Education Conference at Oxford last year. Steps have already been taken to give effect to the decisions relating to the Commonwealth Scholarship and Fellowship Plan, arrangements for the administration of which were outlined in a White Paper issued last November, and a Bill establishing the Commonwealth Scholarship Commission to administer the Plan in the United Kingdom was passed by Parliament in December 1959 (see *Nature*, 185, 214, 271, 505; 1960). On that Plan and on schemes for the training of teachers and for promoting recruitment of United Kingdom teachers for service in Commonwealth countries overseas, the Government proposes to spend £6 million during the next five years to fulfil the undertakings assumed at the Conference; of this sum, about £3·75 million will be required for the purposes of the new Act.

These latter schemes are described in a further White Paper on Commonwealth Educational Co-operation issued in May*. While in the long term the training of sufficient teachers to meet normal requirements can be achieved only by the efforts of the countries themselves, the Oxford Conference agreed that, in the short term, help from other Commonwealth countries could be decisive if carefully chosen and directed towards the most influential parts of the educational system of the recipient country. The United Kingdom Government, therefore, undertook to take steps, in co-operation with the responsible authorities, to make available to Commonwealth teachers additional places in teacher-training institutions in Britain and, within the limits of the funds available for the purpose, to provide grants covering fees and full maintenance to Commonwealth teachers nominated by their respective Governments, so as to enable them to take up these places. The sending country will normally bear the cost of travel to and from the training institution and the British Council will act as agent of the Commonwealth Relations Office and the Colonial Office for the payment of students' fees and allowances, and will be responsible for their reception on arrival in the United Kingdom and for their general welfare. They will be placed by a Commonwealth Bursary Unit in consultation with the training institutions. Provision will be made in the estimates of the Commonwealth Relations Office and the Colonial Office for expenditure of about £285,000 a year, and also some financial provision to afford opportunity to members of the staffs of teacher-training institutions in Britain at which such Commonwealth teachers study, to visit parts of the Commonwealth to see something of the environment in which these teachers will work on completing their training.

The Government also agreed at the Oxford Conference to endeavour to increase the number of teachers who take up posts overseas by special encouragement of recruitment for posts in those areas of the Commonwealth where the shortage of teachers is most acute. Steps are already being taken in co-operation with local education authorities and other responsible bodies to improve the arrangements for seconding and re-employing teachers, for safeguarding their promotion prospects and superannuation benefits in the United Kingdom, and for promoting wider recognition both by teachers and their employers of the value of service overseas in the Commonwealth. The Government has also undertaken to provide, at the request of certain Commonwealth countries unable to offer salary and conditions of service to meet the reasonable needs and expenses of expatriate teachers, special financial assistance to United Kingdom teachers volunteering to fill approved key teaching posts overseas. Such posts may be in primary and secondary schools, teacher-training institutions, technical colleges and universities, and, as defined by the Conference, are, broadly speaking, posts which require teachers with qualifications not locally available in sufficient numbers, or posts in which the teachers will be able to play a creative part in the educational progress of the country concerned.

The measures proposed will include payment of special allowances to bring the salary offered by the local employer up to the level which would have been received in the United Kingdom, and to offset higher living costs and local taxation, as well as payment of fares to and from the United Kingdom and other miscellaneous forms of assistance. Arrangements for posts in universities and university colleges will be drawn up on the advice of a sub-committee of the Universities Advisory Committee of the British Council on which, besides the Council, the universities, the Inter-University Council for Higher Education Overseas, the Commonwealth Relations Office and the Colonial Office will be represented. It will not be made a condition of posts attracting these special allowances that Commonwealth authorities should use an officially recognized United Kingdom recruitment agency; but in view of the considerable experience of the British Council in this field, it is hoped that the services of the Council will be widely used. The White Paper estimates that recruitment of teachers under this scheme will increase from about 75 in 1960 by about 20 a year to 135 in 1963 and succeeding years, and that the cost of this programme to be borne on the estimates for the Commonwealth Relations Office and the Colonial Office will rise to about £700,000 a year by the end of the five-year period.

---

* Commonwealth Relations Office: Colonial Office. Commonwealth Educational Co-operation. Pp. 7. (Cmnd. 1032.) (London: H.M. Stationery Office, 1960.) 6*d*. net.

Apart from these measures, the White Paper points out that the Government hopes to make available a substantial number of additional places for Commonwealth students in technical colleges in Britain during the next decade, and to expand training facilities for Commonwealth students in British industry. The Government is represented on the Commonwealth Education Liaison Committee, set up, together with the Commonwealth Education Liaison Unit, to improve and further Commonwealth collaboration in education. The United Kingdom is also participating in a meeting, probably early in 1961, of Commonwealth experts in teaching English as a second language to study the problems in this relatively unexplored field. The White Paper confirms the acceptance of the Government of India's invitation to attend the next Commonwealth Education Conference at New Delhi in 1961.

In presenting the Bill, which received a remarkable welcome in both Houses of Parliament, the Minister of State for Commonwealth Relations, Mr. C. J. M. Alport, said that in February the Minister of Education, at a Conference on Teachers for the Commonwealth, had advanced several proposals, including the formation of a national council for the supply of teachers overseas, the preparation of a code of secondment for teachers going overseas, and a code of terms for the appointment of such teachers; and it was hoped that in this way and through the provisions of the Bill it would be possible to provide teachers of the calibre and experience required. Mr. Alport said that the Minister was much encouraged by the response at the Conference to his appeal, and Mr. Alport himself repeated the appeal he had made in the debates on the Commonwealth Scholarships Act to employers and to teachers to consider the value and importance of service overseas both to themselves as individuals and to the countries of the Commonwealth.

Mr. Alport emphasized that the success of the scheme would depend primarily on the willingness of individuals to serve abroad for two or three years; but despite the shortage of teachers in Britain he did not believe the numbers required are beyond our capacity. As regards the provision of training facilities in the United Kingdom, Mr. Alport anticipated that the full number of some 400 Commonwealth bursars would be coming to the United Kingdom in the first year of operation. Dealing with the Bill itself, he explained that its provisions had been so drafted as to include bursars who were not actually British subjects or Commonwealth citizens, and to enable the United Kingdom to provide experts other than those of the teaching profession but whose services in Commonwealth countries could be of great material advantage to their educational system as a whole. He estimated that there are at present about 30,000 Commonwealth students in the United Kingdom, of whom about 12,000 come from independent member countries and 18,000 from dependent territories. Of the total, 7,000 are at universities, about 7,000 at technical colleges and 730 already at teacher-training colleges, for which already there has been demands for 300–400 places.

Afterwards, in a written answer to a question in the House of Commons on May 27, Mr. Alport stated that so far some 350 applications had been received for bursaries under the scheme described in the White Paper. The largest group would be experienced teachers taking a wide range of one-year courses in educational theory and practice. Another large group would be taking courses in technical teacher-training and other specialized subjects, and a third group would be receiving courses of initial teacher-training. It was hoped that the first teachers would go overseas under the second scheme during the latter part of this year and that these teachers would cover a wide range of subjects. The United Kingdom authorities are at present assessing the needs of the overseas Commonwealth countries in the light of the information so far received.

Some misgivings were expressed during the debate, and again on May 23 in committee, when the establishment of an Overseas Education Service was suggested, as to whether, in view of the difficulty so far experienced in persuading teachers already teaching in Britain to go abroad for a time, the scheme is likely to succeed. It was emphasized, however, that the posts in question are key posts and in places where recruitment is particularly difficult. Mr. R. Thompson, the Under-Secretary of State for Commonwealth Relations, replying for the Government, said he thinks it unlikely that the allowances would lead to anomalies or create a privileged group or an aristocracy among teachers: the real safeguard, he said, lies in the eligibility of those returning at the end of a contract for re-employment under the scheme. Nevertheless, it was appreciated that, particularly for senior university teachers, there are real difficulties to be overcome in regard to promotion prospects, and much will obviously depend on the interest taken in the scheme by the universities and the reality of their support in such matters.

One point raised in the debate, by Dr. Alan Thompson, concerned the participation of the Union of South Africa. As Dr. Thompson remarked, the educational system of South Africa seems to be in conflict with some of the objectives of the White Paper. Nevertheless, as was pointed out by Mr. I. F. A. de Villiers in *Nature* of March 26, p. 893, South Africa proposes to take part in both the Commonwealth Scholarship Plan and the Commonwealth Education Liaison Committee. This was later confirmed in the House of Commons (*Nature*, July 9, p. 113). Clearly, difficulties must arise, not simply because of the way in which apartheid is practised and the educational principles of the Act are violated in South Africa, but also quite as much through the rejection by the Union Government of the idea of university autonomy. As Sir David Eccles emphasized, this is partly a matter of creating an appropriate climate of opinion, not only to ensure that those who teach overseas suffer no professional handicap on their return, but also to help teachers who are seeking information before they go abroad and to keep local education authorities and the universities continually aware of what is going on and the various needs. In this connexion, Sir David indicated that something like ten visits abroad a year from members of the staffs of training colleges to enable them to familiarize themselves with the local conditions and needs of the teachers they are training in Britain are planned.

Little was added to all this in the debate in the House of Lords on May 30. In moving the second reading, the Earl of Home expressed the Government's appreciation of the co-operation which had been shown by the teachers' representatives, by the local authorities, by the churches, and by the teacher-training institutions, which had pledged themselves to make this scheme work. They had devised a draft scheme of secondment to which the Government hoped all the education authorities would subscribe and which it hoped they would all adopt. Lord Home also said that Dr. V. S. Jha, lately vice-chancellor of Banares Hindu University, would be the first director of the Commonwealth Liaison Unit. In both Houses of Parliament there was thus evidence of the imaginative response and enthusiasm for which Lord Home appealed at the time of the Conference last year, and that in Parliament at least it is fully realized that assistance in educational development is one of the most important forms in which technical aid can be given to the under-developed countries, within and without the Commonwealth.

That this is not more generally recognized is unfortunately only too true, as the reluctance of the Federal Government to take over the Copperbelt Technical Foundation set up three years ago by the Anglo-American Corporation and the Rhodesian Selection Trust shows. The second of these two mining groups was concerned with the great need to train Africans for more responsible work, but when the Technical Foundation was launched it admitted, and still admits, Europeans only. When, during the copper slump, the Government of Northern Rhodesia was approached for a grant, it made such a grant contingent on the Foundation becoming multi-racial and admitting Africans, as the Rhodesian Selection Trust had desired from the start. The Federal Government made such a grant, however, without any conditions but did not desire to take over the running of the institution. The Government of Northern Rhodesia is debarred, however, from taking over the Foundation as it stands, because European education is a Federal responsibility; but it could, and is willing to, do so if the Foundation is thrown open to suitably qualified youths on merit and regardless of colour, since African education, including apprenticeship and the type of instruction given at this institution, is a territorial responsibility.

Meanwhile, the importance of trained man-power generally and of technical education in particular in like territories is emphasized from one source after another—by Mr. Kenneth Younger in his Sydney Ball Lecture at Oxford last November, and in a subsequent book, by Dr. B. V. Bowden, in articles on the universities' task in Ghana and on technical education there, based on his recent visit, and in the latest report from the Colonial Development Corporation. Dr. Bowden believes, indeed, that if there were an adequate supply of technologists, Ghana need not look elsewhere for most of its professional administrators. He anticipates that if its universities in the next few years can educate the scientists and technologists who are needed in ever-increasing numbers as the country takes its place in modern society, a vital intellectual stimulus would be provided to both staff and students, apart from the benefit of its impact on industry, agriculture and public health; but an essential part of that programme is an active programme of research, especially in agriculture, medicine and engineering, into the formidable technological programmes which confront the country to-day.

In fact, however, Dr. Bowden regards technical education in Ghana as essentially a pyramid without a base, because there is no adequate provision for the education of the craftsmen, charge-hands, foremen, under-managers, etc., whom the graduate engineers, for whom educational facilities are provided, will need. If Ghana is not to use most of its graduates as technicians and clerks, he believes that country will need to spend very much more on non-university education than it does on the universities, and it may well be that in this field of technical education the help which could be forthcoming through the schemes outlined in the White Paper on Commonwealth Educational Co-operation may be most valuable and most needed. Dr. Bowden refers, moreover, to the need for more opportunities for engineering graduates in Ghana to gain practical experience; and it would seem that his suggestion that the Government of Ghana should arrange for its graduates to go abroad to join one of the great firms that have organized postgraduate apprenticeships for many years is at least possible, under the further measures contemplated in the final paragraph of the White Paper.

THE GALATHEA EXPEDITION

Galathea Report

Scientific Results of the Danish Deep-Sea Expedition round the World, 1950–52. Edited by Dr. Anton F. Bruun, Captain Sv. Greve and Prof. R. Spärck. Vol. 1: Pp. 260+8 plates. 90 D.kr. Vol. 2: Pp. 253+4 plates. 75 D.kr. Vol. 3: Pp. 87+85 plates. 60 D.kr. (Copenhagen: Galathea Committee, 1956–1959.)

When the Galathea Expedition was planned, the deepest parts of the ocean floor had yet to be explored. Accordingly, the main aim was to sample the benthic fauna, if indeed this existed, at levels beyond 6,000 m. Such deep regions, in the form of trenches, are found principally in the Indonesian area and in the Western Pacific Ocean.

These three volumes and the narrative published in 1956[1] contain ample evidence that this exacting task was accomplished with conspicuous success. This work (and that carried out by the Russians since 1949) has shown that the deep-sea trenches contain limited but distinct communities of invertebrates. Dr. Anton Bruun, the leader of the Galathea Expedition, refers to such animals as the hadal fauna[2]. The recent dive of the U.S. Navy Bathyscaphe *Trieste* in the Challenger Deep (Marianas Trench) has now revealed that fishes may also range into the hadal regions.

Most of the papers in these reports deal with groups of benthic invertebrates taken at depths beyond 6,000 m. (Volume 1: Actiniaria (Carlgren); hydroids (Kramp); Echinoidea, Asteroidea and Ophiuroidea (Madsen); Holothuroidea (Hansen); Crinoidea (Gislén); Polychaeta (Kirkegaard); Isopoda and Tanaidacea (Wolff).) Volume 1 also contains a full report on the deep-sea Ascidiacea (Millar) and papers on two bathypelagic groups (Vampyromorpha (Pickford) and whale-fishes (Rofen)). A complete account of the Pycnogonida (Fage) will be found in Volume 2, which also contains papers on free-living nematodes (Wieser) and on certain new species.

Considering only the papers concerned with animals from the hadal zone, nearly half the species (40 out of 87) have proved to be new. This certainly suggests that the deep-sea trenches contain a special fauna, although certain contributors point out that this idea may need to be qualified when the abyssal regions of the deep-sea floor (2,000–6,000 m.) have been more thoroughly explored. The trophic structure of the hadal fauna also seems to be distinctive. It appears from these and Russian reports that predatory animals such as the asteroid and ophiuroid echinoderms and the decapod crustaceans are scarce or absent in extreme oceanic depths. The greater part of the benthic biomass generally consists of the ooze-eating holothuroid echinoderms. Where conditions favour higher rates of sedimentation, the particle-ingesting pogonophorans may be very abundant.

The station list in Volume 1 will reveal that the expedition devoted much time to trawling and dredging in the Philippine Trench. But before this could be attempted, the trench was thoroughly surveyed by echo-soundings, and an account of this work is given by Kiilerich. Volume 1 also contains the results of two other important aspects of the expedition's programme, the measurement of oceanic productivity (Steemann Nielsen and Jensen) and the study of deep-sea bacteria (ZoBell and Morita).

The radioactive carbon technique now widely used for measuring marine plant productivity was developed just in time for the expedition. A full account of the method and measurements, which were made in all three oceans, is given, and the report ends with a comprehensive and valuable survey of the physical and biological background to oceanic productivity.

Deep-sea bacteria obtained from sediments in the trenches were found to look very like common soil forms, but were shown to grow preferentially or exclusively at the pressure and temperature of their environment. ZoBell and Morita calculate that the carbon content of the standing crop of bacteria in a square metre of sediment (1 centimetre in thickness) is about 2 milligrams. Since marine bacteria are able to oxidize most kinds of organic matter, the authors suggest that these organisms may well be an important food source for mud-eating and filter-feeding invertebrates. But they also remark that nothing is known of the productivity of deep sea bacteria.

Zoologists and palæontologists will welcome the superbly illustrated, detailed account of the anatomy of *Neopilina galatheae* by Lemche and Wingstrand, which takes up most of the third volume. The authors clearly show that this mollusc belongs to the class Monoplacophora, order Tryblidiacea, a group represented at the time of writing by two species, but otherwise known only as fossils in Cambrian, Silurian and Devonian deposits. The metameric repetition of organs, which is most marked beyond the third pedal retractor nerve, is well demonstrated. The systematic and phylogenetic implications of these and other findings are to be considered in a later report.

The last paper in Volume 3 is a short but interesting study by Munk of the pair of plate-like head organs in the abyssal myctophoid fish, *Ipnops murrayi*. The cellular make-up of these structures plainly shows them to be modified eyes, a most curious transformation, but one that may not be confined to the genus *Ipnops*. There is evidence that some parallel may be found in the eyes of the bathypelagic whale-fish, *Ditropichthys storeri*[3]. Closer investigation of this species would now be of great interest.

To conclude, these handsomely produced reports are striking proof of what has been accomplished in oceanic biology during the past ten years. But they are also bound to be a measure of what remains to be done. The thorough, large-scale investigation of the ocean that is now required is beyond the resources of any single nation. It is to be hoped that international effort, such as that being contemplated for the Indian Ocean, will meet this need.

STABILITY AND CONTROL OF FLIGHT

Dynamics of Flight

Stability and Control. By Prof. Bernard Etkin. Wiley Books in Space Technology. Pp. xiv + 519. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1959.) 120*s*. net.

THIS is a modern treatment of the fundamental theory of the stability and control of aircraft. Performance and flutter issues have been specifically excluded. Numerical examples are used to illustrate applications and typical results.

The reader is assumed to be familiar with basic mechanics, aerodynamics and with complex numbers and differential equations. An appendix gives a résumé of vector analysis. On this basis the static stability of an aircraft in its equilibrium states is first analysed and the influence on the stability of various controls, etc., is discussed. The general equations of unsteady motion are then developed in a systematic way. The author starts with the aircraft as a single rigid body and then elaborates on the equations so obtained by adding in turn the effects introduced by the presence of spinning rotors, the control surface movements and finally the effects of elasticity in the system. An attractive feature of the presentation is the fact that from time to time the reader is reminded of the assumptions behind the various sets of equations by having these collected and listed for him.

Each of the stability derivatives contained in the general equations of motion is discussed next. Formulæ for their evaluation are given or, where this is not possible, the qualitative dependence of the derivative on the perturbation quantity is described. Three appendixes give about sixty pages of formulæ, tables and graphs relevant to stability derivatives, the standard atmosphere, mean aerodynamic chord and centre, etc. The data quoted are taken mainly from the National Advisory Committee for Aeronautics Reports and Royal Aeronautical Society Data Sheets. The National Advisory Committee for Aeronautics notation of stability derivative is used throughout the book. The author directs attention to certain differences in definitions used in Great Britain and the United States.

In successive chapters the stability of small perturbations in the longitudinal and the lateral motions is analysed using the differential form of the equations of motion. Since the subject-matter of the remainder of the book can only be treated fully by the use of mathematical techniques based on Laplace transforms, frequency responses and random functions, a chapter is devoted to an explanation of these techniques. The Laplace transform and frequency response-approach is then used to study the response of the aircraft to actuation of its control surfaces.

The next topic to be treated is that of flight in turbulent air, and here the approach is centred on analysis in terms of the power spectrum of the turbulence.

On the assumption that the aircraft motion is known, there may be occasion to determine (*a*) the input action, given the aircraft parameters, or (*b*) the aircraft parameters given the input action. A chapter is devoted to such inverse problems. This is a topic of considerable practical interest and the value of the short outline given would have been greater had some notes been included on some of the practical difficulties involved.

The last three chapters give the reader an outline of up-to-date applications and techniques by discussing in turn, automatic stability and control by means of feed-back devices, specialization to missiles, and finally the fundamentals of machine computation and simulation. These chapters are brief but nevertheless valuable introductions to very large subjects. This is a carefully prepared and well-presented book which covers a very wide field in a very competent manner.

REFERENCE BOOK OF THEORETICAL PHYSICS

Manual of Mathematical Physics

By Paul I. Richards. Pp. xi+486. (London and New York: Pergamon Press, 1959.) 110*s*. net.

THE author states in his preface: "The goal of this book is to condense established theoretical physics, its applications and its mathematical equipment into a single reference volume of reasonable size without sacrificing either logical continuity or fundamentals".

This seems to be a hopeless attempt. The book has, however, a distinguished German predecessor. "Die mathematischen Hilfsmittel des Physikers", by E. Madelung, is a collection of formulæ and theorems concerning a wide field of advanced topics in theoretical physics which for four decades has been of invaluable assistance to research workers. The influence of Madelung's work on the present book is obvious and beneficial, but emphasis is now shifted to some extent from formulæ to verbal argument.

A 'physics' section covers classical mechanics, electrodynamics and optics; thermodynamics and statistical physics; relativity and the quantum theory of matter and radiation. Both the general principles of the theories and their applications to special problems are taken into account. In addition a number of recent branches of theories are included, and circuit theory and other subjects of technological importance are added. A 'mathematics' section deals with the calculus, complex functions, series expansions and differential equations; integral equations and Hilbert spaces; modern algebra, vectors and tensors; numerical methods, probability and linear programming, to name the most important headings.

It need scarcely be said that the accommodation of this vast amount of material is possible only by very concise wording. This obviously renders the volume unintelligible to all but fairly expert readers. The value of the book should accordingly be assessed by its possible use to competent research workers.

This use is unfortunately somewhat limited because the presentation of the subject does not conform with the author's claim in the preface. The 'physics' section does not show much logical continuity; rather it would appear to be an assemblage of unconnected and incomplete statements. The shortage of space does not prevent the author from indulging in unnecessary verbosity whereby significant points in explanations are lost.

The 'mathematics' section is on the whole better presented, but is burdened by numerous formulæ the origins, applicability and significance of which are not given. 1,200 words are used for the subsection 'signal flow diagrams', which appears to be a method for solving simultaneous equations. I was unable to derive from the text any instruction for operating by this method; nor is there any result shown from which the principles of this method could be inferred. Contour integration is dealt with in 100 words, no result or example being presented. The Lebesgue integral is discussed in 250 words—which should be sufficient for a book of this kind—but no definition of that concept is included. There is an adequate table of Laplace transforms, but no corresponding table of Fourier transforms. These examples may show that also the 'mathematics' section is of limited use only.

So far as the verbal text is concerned the book is scarcely any better than a list of technical terms of theoretical physics and applied mathematics. This shortcoming is all the more surprising as the author repeatedly shows that he has mastered the subject and would be capable of saying much in few words. Presumably he believes that his source book is of interest to some class of readers, whoever they may be.

If the book is regarded as a collection of formulæ it may still be useful to research workers. They may save appreciable time and effort if a formula can be found in the present volume and need not be searched for in some treatise. R. EISENSCHITZ

EVOLUTIONARY DIVERGENCE

Evolution above the Species Level

By Prof. Bernhard Rensch. Pp. xvii+419. (London: Methuen and Co., Ltd., 1959.) 63*s*. net.

THE distinguished author of this book has long been known for his extensive studies on the island distribution of birds and other vertebrates, and of land snails. This work was done especially in the Malay Archipelago, on which he wrote a valuable treatise in 1936 (which for some reason he has omitted from the bibliography). It led him to take a profound interest in the formation of races and species, and their evolution. The word 'Rassenkreis' was coined by him. His monograph in 1929 on "Das Prinzip geographischer Rassenkreise und das Problem der Artbildung" is a classic. Later on he became engrossed with wider questions about the natural processes of evolution, not only in races and species, but also in the divergence and segregation, if that is the right word, of higher taxonomic groups.

The German edition of "Evolution above the Species Level" was published in 1947, but enhanced in a later version in 1954, of which this English edition is essentially a direct translation by Dr. Altevogt. It is a very solid book, crammed with argument and cited evidence, and well illustrated with text drawings. Though its style is certainly pretty heavy and liberally laced with ponderous terms like kladogenesis, archallaxis, bradytely and hylopsychic, the argument is clearly and powerfully developed. The central idea that the author seeks to prove is that the higher grades of phylogenetic branching can be explained by the same orthodox beliefs about natural selection as can race formation and speciation. This involves him naturally in an all-out attack on such directional theories as orthogenesis, which he takes considerable trouble to demolish.

Prof. Rensch has an enormous acquaintance with the literature on evolution, including many aspects of comparative anatomy and development, and he uses many different sectors of zoology as channels of argument, which are gradually united to try to prove the central theme. Although the general integrity of this sifting and assembling process is obviously high, there is a tendency to accept other people's facts and conclusions at their face value, instead of critically testing their authenticity. I was, for example, startled at being quoted in support of the view that there is no natural population balance in animal communities. The reader may perhaps feel as if he were walking through a very well-arranged museum, in which the tickets on each exhibit instruct him clearly what to believe. But the theories are put forward logically, and on the whole cogently. If one believes mutation and natural selection to be the sole basis of race and species formation, the rest of the argument follows fairly convincingly. But one should remain at liberty to wonder if the first assumption contains the whole truth about evolution. The evidence against such ideas as orthogenesis is powerfully marshalled and convincing, though it could partly stand alone on its own merits.

Two special chapters may be mentioned that are interesting, but slightly out of the main stream of argument: one on the absolute rate of evolution in producing taxonomic groups of different levels (that is to say, species, family, order), and another about the evolution of higher psychic processes. But the main message is continually hammered at us: "The evolution of new structural types and of new organs needs no other explanation than specific and generic differentiation, i.e. the combined effect of mutation and selection". The book is beautifully printed, and there is a vast and useful bibliography.

C. S. Elton

THE TWO HEREDITIES

The Future of Man

By Prof. P. B. Medawar. (The B.B.C. Reith Lectures, 1959.) Pp. 128. (London: Methuen and Co., Ltd., 1960.) 10*s*. 6*d*. net.

GOOD lectures when published often make poor reading. The 1959 Reith Lectures make good reading, though as lectures the author views them unfavourably: "they were too closely reasoned", he writes, "and often made unfair demands on the listener's attention". The conciseness of expression and the balance of phrases in neat antithesis, qualities which make listening difficult, are a virtue in print and in scientific writing a rare merit. Explaining the concept of 'fitness', for example, he writes: "All the people alive 100 years from now will be our descendants, but not all of us will be their ancestors". The reader can pause and look again—and often will in reading this text: the spoken sentence is past before the listener is aware that something important has been said.

The approach in the earlier lectures may have discouraged some of the less-sophisticated among his audience. "I decided that these lectures were to be about the process of foretelling (the future of man) rather than about what is actually foretold." In each of various aspects of forecasting human development, Prof. Medawar shows the complexity of the mechanisms involved. For example, on the relation between intelligence and fertility his lecture opens with five possible explanations of this relation and proceeds to show that the inference of a decline in national intelligence is equally complicated by difficulties. But this kind of discipline in thinking about the implications of the past half-century of research in human biology is precisely what is most needed. Since so few biologists have been willing to discuss their subject on this scale and in this strict way, the field has been left to the naïve thinkers and the propagandists to proclaim that medical science is preserving an unfit population, that birth control is bound to have evil consequences, that the laws of genetics have an over-riding authority. The positive contribution of these lectures is in their demonstration of the muddled thinking of the upholders of the doctrine of 'geneticism'—"the idea that man's genetic constitution is not merely important but all-important".

Do genetical laws set predictable limits to man's future development? This is the central theme of the lectures, and Prof. Medawar's position is in sharp contrast to that of the older social biology. The answer, introduced in the final pages, is that man has two systems of heredity, one genetical, one cultural: the interaction of these two systems changes the prospect entirely. This is really the beginning, not the end, of the topic of the future of man; but it takes the topic beyond biology into the social sciences.

The bringing together of these two systems of heredity suggests a comparison with another widely discussed lecture of 1959, the Rede Lecture, which showed the need for merging our two cultures, the scientific and the literary. Of recent years, the non-scientific world seems to be assimilating quite successfully the simpler concepts of physics, but is still far behind in its grasp of the trends in the biological sciences. These Reith Lectures provide an example of the kind of thinking and talking that must be done if the more recent developments of biology and genetics are to win their proper place in the general education and the intellectual culture of our population.

J. D. NISBET

BIOCHEMISTRY AND HEREDITY

The Chemistry of Heredity

By Prof. Stephen Zamenhof. (Publication No. 365, American Lecture series. A Monograph on American Lectures in Living Chemistry.) Pp. xi+106. (Oxford: Blackwell Scientific Publications; Springfield, Ill.: Charles C. Thomas, 1959.) 34s. net.

THE great and diversified scientific effort which we are witnessing to-day all over the world has brought with it problems of communication. The expanding list of scientific journals bears witness to the volume of publications by which scientists are attempting to inform others of their discoveries. Such publications, however, may appeal only to like-minded specialists. Nevertheless, scientists of all disciplines as well as medical practitioners do, from time to time, feel the need to acquaint themselves with the state of knowledge in a particular field. Another, much larger, group of potential readers interested in the facts of scientific advance is the general public. Many of its members have helped to finance "the enlightened programs of research grants in our country" to which Prof. Zamenhof so rightly pays tribute in the dedication of his book. In the choice and presentation of the material of this monograph the author has apparently tried to aim at the professing scientists, the medical readers as well as the curious but unqualified.

In the introduction the author prepares the ground for the subsequent discussion of the possible mechanisms for the transmission of heredity by chemical compounds. Prof. Zamenhof then lists in outline required properties of heredity determinants and gives examples of classes of biological systems which must reasonably be under their genetic control. In the second chapter evidence is given for the central thesis of this book that heredity determinants are chemical substances. The non-specialist or even student is gently led towards the objective that deoxyribonucleic acid is the most plausible carrier of heredity. Due weight is here given to the direct proof for this postulate where viruses are concerned, which Prof. Zamenhof puts beside the almost incontrovertible but indirect evidence for the genetic role of deoxyribonucleic acid in higher organisms. A résumé of the structure of the nucleic acids is then followed by a discussion of the implications of those biochemical experiments by which nucleic acids have been synthesized *in vitro*. Under the heading "Mutation" the author regrettably only touches on hypotheses and on the genetic concept of carcinogenesis. Perhaps he wished to keep the account of work so close to his own promising field short for the sake of clarity. The facts of cytoplasmic inheritance are authoritatively stated and the subject well set within the context of the book. The remainder of this monograph is concerned with research in biochemical genetics: studies with micro-organisms and the examination of hereditary defects in man. The reader is given a hint of the problems, theoretical and practical, which confront investigators in this field.

This is a book that can be recommended to scientists and medical men who wish to widen their horizons, and to students providing they can persuade their library to buy it. The problem of how to present scientific facts, let alone the complexities of the chemistry of heredity, to the lay reader has not been brought closer to a solution by this volume.

The book is well produced; misprints are practically absent, but the text gives examples of bizarre notions of how to divide words. The comprehensive bibliography should be useful to all readers alike.

P. COHN

RECENT AMERICAN RESEARCH IN NEUROPSYCHIATRY

Chemical and Molecular Basis of Nerve Activity

By David Nachmansohn. Pp. xi+235. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1959.) 7.50 dollars.

International Review of Neurobiology

Vol. 1. Edited by Carl C. Pfeiffer and John R. Smythies. Pp. xii+383. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1959.) 10 dollars.

Neuropharmacology

Transactions of the Fourth Conference, September 25, 26 and 27, 1957, Princeton, N.J. Edited by Harold A. Abramson. Pp. 285. (New York: Josiah Macy, Jr. Foundation, 1959.) 5 dollars.

THESE three books cover recent American researches on various aspects of the nervous system. The emphasis is on the nature of transmission, the chemical isolation of naturally occurring substances believed to have physiological or pathological importance, and the effects of drugs. In each case, the publishers are to be congratulated on having produced a handsome volume, well illustrated and carefully indexed. The bibliographies are satisfactory. With some qualifications, it may also be said that the authors, too, have given us something of which they may be proud.

Nachmansohn's book is the only monograph. It represents the results of nearly a quarter of a century's work by the author and colleagues on the metabolism of acetylcholine and its associated enzymes. It is a well-written, interesting, and coherent account of the progress which has been achieved. Beginning with a discussion of the physical events during nerve-activity, the author successively deals with a hypothesis of chemical transmission, the high speeds at which hydrolysis can take place, and substances which are capable of inhibiting the enzymes of this system. He goes on to describe the physicochemical exchanges in the electric organs of certain fish, and then makes a bold attempt to define in detail the rôle of acetylcholine in conduction. Here, there is a useful diagram to explain the author's views. The way in which nerve-gases, insecticides, and antidotes may be fitted into this scheme is next discussed. The book closes with chapters on the complex nature of the changes in the permeability of conducting membranes and on the problems of synaptic transmission. In his concluding remarks, the author freely admits that we are only beginning to understand the "chemical forces and structural arrangements" of these membranes.

The editors of "The International Review of Neurobiology" write in their preface that their aim is to enable workers in many different, but related, fields to keep abreast of recent advances. This book is composed of eight articles, each by different authors. The first two are mainly electro-physiological. The third and fourth are neurochemical. The fifth is on the psychophysiology of vision, with particular reference to the effects of various stresses (for example, anoxia and induced hypoglycæmia) and of a number of drugs. The last three articles are concerned with metabolic studies in disease.

As is almost inevitable with such a conglomeration of contributors, the merits of the articles vary a good deal. Particularly interesting were W. R. Adey on the rhinencephalon and epilepsy, Catherine Hebb on chemical agents of the nervous system, and Carl C. Pfeiffer on parasympathetic humors. The least impressive were the last three articles, which attempt to relate products of abnormal metabolism to schizophrenia and even multiple sclerosis.

The volume entitled "Neuropharmacology" has the weighty disadvantage that it is an account, in the form of a dialogue, of a conference which was held more than two years before the book was published. For the reader to-day, it thus cannot altogether avoid the air of staleness which clings to an old newspaper discovered by chance in an attic. Such a document may, and often does, carry an absorbing transitory interest for him who vividly recalls the events described; yet may altogether fail to hold the attention of those who have not any reason to remember. In addition, dialogue is a challenging form of literary endeavour. Perhaps even Plato's genius does not always avoid stultifying thought by irritating changes of direction, as the argument is developed. A mode of human communication which is inevitable, and indeed proper, in a conference room too easily becomes irksome if it is inscribed in print.

Dr. Fremont-Smith, in explaining the scope of the book, makes a convincing plea for the usefulness of the conference which is reported; but admits that the form of the publication has already given rise to criticism and that a few critics have stated that they would have preferred a "depersonalised summary". If, by some device, the opening speakers had been allowed in this volume to complete their themes unobstructed, as, after all, usually happens in conferences, there would have been less reason to object to a subsequent discussion. In this presentation, we are not even allowed a summary of the opener's remarks.

Four subjects are discussed: (1) "The Effect of Respiratory Poisons and Anoxia on Siamese Fighting Fish in Relation to LSD–25 Reaction" (Dr. Abramson); (2) "Clinical Studies with Taraxein" (Dr. Heath); (3) "'Stop' and 'Start' Systems" (Dr. Lilly); (4) "Some Relations between Chemical Structure and Physiologic Action of Mescaline and Related Compounds" (Dr. Alles).

Dr. Abramson's article includes piscine illustrations which are intriguing, but his interlocutors are allowed to get at him too soon. Towards the end of his second page (p. 13), the dialogue runs as follows:

"*Abramson*. I might add here that we have data on what the 1-methyl and what the 1-acetyl derivatives of *LSD*–25 do to man.

Marrazzi. You must have had a reason for not using the standard presentation of the log of the dose, which would straighten out the curve.

Abramson. I prefer to deal with the actual data rather than a log.

Hoagland. Are they log relationships or semilog plots?"

Thereafter, Dr. Abramson gets hounded, so to speak, from log to log or from plot to plot for several pages, before he or the scientific dogs who pursue him return to the absorbing human trail.

Dr. Heath fails to impress with taraxein. It is clear from the voices of the hounds after him that they fully realize that the scent which he is laying is not absolutely reliable.

Dr. Lilly's 'stop' and 'start' systems are of great interest. Electrodes accurately and permanently implanted into the brains of monkeys enable him to define certain areas, the stimulation of which gives rise to characteristic behaviour. Moreover, the dogs of dialogue let him run longer distances before bringing him to bay.

Dr. Alles gets the fairest start of all, and is extremely informative on the structure and action of phenylethylamines for 20 or 30 pages, before the pack catch up with him and pull him down. Thereafter, the run of the argument deteriorates, until he escapes with a second wind for five or six pages towards the end.

This book would have much to be said for it, were it not for its regrettable art-form. D. H. BRINTON

ADVANCES IN VETERINARY SCIENCE

Advances in Veterinary Science

Vol. 5. Edited by C. A. Brandly and E. L. Jungherr. Pp. xi+450. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1959.) 14 dollars.

THE fifth volume of "Advances in Veterinary Science" embraces seven chapters of varying interest to veterinary surgeons in Great Britain and Overseas.

The first chapter, dealing with the examination of the eye and eye operations in animals, breaks new ground as well as consolidating knowledge gathered from a wide range of experience. Surgeons, especially those interested in small-animal surgery, will find in this chapter a wealth of valuable information. In the second chapter, '*Q*' fever is dealt with in all its aspects and, being a relatively 'new' disease, will be studied with more than topical interest by both medical and veterinary workers interested in public health.

Rabies forms the subject of the third chapter. While it might have been thought that everything about this, one of the oldest diseases known to mankind, was already understood, readers will find in this chapter much new information on the diagnosis and control of the disease. New human rabies vaccines of duck-embryo and chicken-embryo origin are discussed and their promise in general use assessed. Of special interest to workers in Africa are the chapters on eradication of the tsetse fly from Zululand and that on theilerioses.

To those working in the North American continent the subject of infectious bovine rhinotracheitis, which is dealt with in the sixth chapter, will be of special interest. The virology of this disease is dealt with at some length, and the interesting and fundamental observations that viruses are able to mutate and modify their tissue affinity and host specificity will no doubt be welcomed by many workers in this field. The last chapter deals with tissue culture in veterinary medical research, and in the discussion on this chapter a number of vital questions are posed, prominent among them being the question of the simultaneous vaccination of cattle against a number of viral diseases and the possible interference between viral agents in a mixed vaccine.

The subjects embraced in this volume do not lend themselves to profuse illustration except that covered by the first chapter, in which a number of excellent photographs and diagrams are supplied. The references and indexes are, as in the previous volumes, most comprehensive and leave nothing to be desired. This fifth volume is a worthy companion to its predecessors and will further enhance both the academic and practical value of the series.

H. BURROW

FLORA OF THE ZAMBESI BASIN

Flora Zambesiaca

Mozambique, Federation of Rhodesia and Nyasaland, Bechuanaland Protectorate, Vol. 1, Part 1. Edited by A. W. Exell and H. Wild. Pp. 336. (London: Crown Agents for Oversea Governments and Administrations, 1960. Published on behalf of the Governments of Portugal, The Federation of Rhodesia and Nyasaland, and the United Kingdom.) 25*s*.

THE publication of the first part of the "Flora Zambesiaca" is the first fruit of many years of co-operation between botanists and administrators of several botanical institutions and almost as many governments; the second part is already in the press and should appear later this year.

The area covered includes the vast territories of Africa to the south of the former Congo Belge and Tanganyika, to the east of Angola and South West Africa, and north of the Union of South Africa, and, as is claimed in the introduction, the aim of uniformity of treatment within certain limits of freedom has been admirably attained. This in itself is a remarkable testimony to the practical uniformity of taxonomic methodology. In no family or genus treated in this first part is there any evidence of mere specimen—as distinct from species—description, but at the same time all the contributors have taken care to avoid inclusion of discontinuous variables in the same taxon.

During the preparation of the work, all contributors have published necessary notes, nomenclatural and taxonomic, in a series of papers in the *Boletim da Sociedade Broteriana*; there are only four 'new' names in the Flora. The introduction is printed in English and Portuguese and the glossary, adapted from that of the "Flora of West Tropical Africa", although arranged according to the English entries, includes also the Portuguese equivalents. The key to families has been produced by J. E. Dandy following the pattern of, and adapted from, Hutchinson's "Families of Flowering Plants". The second edition of the latter was not available when the key was prepared. The key occupies twenty-four pages, and Portuguese readers may think that a version in their language might be an improvement, though it is understood that the English key has been reprinted and has found a ready market among them.

The general text follows the well-tried system of Bentham and Hooker, with some modifications. The gymnosperms, by J. Lewis, with two genera and six species of cycads, two species of *Podocarpus* and one each of *Widdringtonia* and *Juniperus*, presented no great taxonomic difficulty, but a uniformity of treatment with that of Melville in the "Flora of Tropical East Africa" is readily discernible. The two texts were prepared independently, one at the British Museum and one at Kew. The treatment of the Ranunculaceae by Exell and Milne-Redhead is essentially the same as that of the earlier flora, some of the errors of the latter being now corrected. Dr. Robson is to be congratulated on his bold treatment of the difficult family Annonaceae. There is no evidence that his new synonymy is too extensive; it is a clear testimony to his painstaking examination of all relevant available literature and specimens with a view to determination of real specific limits and intraspecific variation. The same author is also responsible for the family Violaceae. The Menispermaceae, by Dr. G. Troupin, follow the same general pattern as the same author's treatment of the family in the "Flora of the Belgian Congo", but he has not been afraid to introduce improvements and corrections wherever these have become necessary.

Of the other larger families included in the present part of this Flora one might mention Capparidaceae and Flacourtiaceae by Dr. Wild, and Cruciferae and Polygalaceae by Mr. Exell. Other contributors are Dr. F. A. Mendonça (Nymphaeaceae), Mr. P. Taylor (Resedaceae) and Dr. G. Cufodontis (Pittosporaceae).

Several artists have contributed to the 58 plates of very fine line drawings illustrating no fewer than 80 genera. (It should be noted that the figure and text concerning *Cladostemon kirkii* are erroneous. The fruit of this species is some 22 cm. in diameter.) Most of these have been prepared specially for the Flora by Miss L. M. Ripley and Miss G. W. Dalby; some have been reproduced from Hooker's "Icones Plantarum" by permission of the Bentham-Moxon Trustees; some are reproduced from the "Flora of Tropical East Africa". All of them are well chosen, beautifully executed and printed and should help considerably in generic identification. The coloured frontispiece depicting *Cleome diandra* Burch. is a most satisfying picture; it was adapted from a field water-colour sketch made by the late Mrs. E. J. Lugard (not "H. E." as in the legend) when she accompanied her husband on his expedition to Ngamiland in 1898.

One could wish that Mr. Exell's account (pp. 23–34) of the history of botanical exploration in the area had been much more extensive. Although detailed itineraries such as that given for Sir John Kirk by Miss Hayes (pp. 35–37) may be unnecessary, more details concerning other collectors would have been of considerable interest and permanent value. One feels that undue attention has been given to limiting the size of this part, without due regard to the possible value of recording much of the bibliographical and biographical research which the contributors must have carried out. In view of the fact that the complete Flora will run to some thousands of pages, the editors might well have used more than a mere 78 pages for introductory matter which includes title-page, preface, glossary and key to families, as well as a brief selected bibliography and list of abbreviations. An opposite policy has been followed by the editors of "Flora Malesiana", in which some hundreds of pages have been devoted to introductory matter in each of the two volumes so far published. It is understood, however, that Mr. Exell proposes to rectify this in a separate work.

The lay-out of the general text is a compromise between completeness and utility. The descriptions of families, genera and species have been pruned to essentials, with emphasis on characters that are regarded as diagnostic for each category. References to the literature are also pruned to avoid mere repetitions; in the case of genera only the original place of publication is given, though many readers might have been pleased to have also a reference to a recommended later work. No reference at all is given for families. Specimen citation also is limited to a single specimen from each of the large areas marked on the folded map provided in a cover pocket, and this is followed by a brief indication of total distribution and habitat.

Dichotomous keys to genera and to species need to be tested over a long period before their true value can be assessed, but it is usually possible to estimate their workability by inspection. In this Flora considerable pains have been taken to use absolute contrasting characters; mere size differences have been used but rarely. Such treatment inspires a confidence which in the tests I have made has been shown to be well founded.

The text and illustrations have been carefully edited, and typographical errors are few and unimportant; even on p. 332, where the two lines appearing at the top of the page have jumped from the bottom, no inconvenience will be caused. The book is dedicated to the memory of the pioneer collectors in the area, Loureiro, Baines and Kirk. Everyone concerned is to be congratulated on the production of a really useful modern Flora. A. A. BULLOCK

CELLS AND THEIR ENVIRONMENT

Cell, Organism and Milieu

Edited by Prof. Dorothea Rudnick. (Seventeenth Symposium on the Society for the Study of Development and Growth.) Pp. v+326. (New York: The Ronald Press Company, 1959.) 8 dollars.

The Relationship between Nucleus and Cytoplasm

Proceedings of the Symposium held June 9–13, 1958, at l'Université Libre de Bruxelles, Belgium. Edited by Dr. R. J. C. Harris. (*Experimental Cell Research*, Supplement 6.) Pp. viii+276. (New York: Academic Press, Inc., 1959.) Cloth bound 12 dollars; paper bound 10 dollars.

THE value of symposia increases with the amount of organization and integration of the topics which are discussed, and, all too frequently, so-called symposia become exercising grounds for well-trained hobby-horses. In "Cell, Organism and Milieu" are gathered together ten papers given at the seventeenth symposium of the Society for the Study of Development and Growth. Certainly the papers all deal with aspects of development or growth, but that is almost the beginning and the end of their connexion with each other. The book has little more coherence than a single volume from almost any scientific journal. Individually some of the papers are of great interest, but it is unlikely that they will all appeal equally to any one reader.

A review article on the physiology and biochemistry of the mammalian blastocyst rubs shoulders with papers on auxins in relation to fruit-growth and on polyploidy in root development. The first paper in the symposium, by Wilde, makes some attempt at a synthesis of the actions of some of the internal and external biochemical factors on the behaviour and development of cells, and the article ends with a description of the remarkable formation of hybrid multinucleate muscle fibres by the fusion of the cytoplasms of mouse and chick myoblasts. Hoffmann-Berling directs attention to the similarities and differences among the various cellular elements responsible for muscular contraction and other forms of cell movement, and emphasizes by models the universality of the relationship between adenosine triphosphate and contractile proteins. The problems of contraction and the control of contractile processes are taken up again by Csapo in relation to uterine muscle. This involves a discussion of the actions of the gonadal steroids on the cell membranes of the uterine muscle. Moog continues with a discussion of the action of cortisol on the development and activity of phosphatases, and Schneiderman and Gilbert make the suggestion that the 'juvenile hormone' in insect development is a steroid. Finally, a paper by Loomis emphasizes how science advances in water-tight compartments. The importance of carbon dioxide tension has been part of the stock-in-trade of mammalian physiologists since the days of J. S. Haldane, Sir Joseph Barcroft and L. J. Henderson. Its importance is now emphasized in relation to the growth and development of *Hydra* and other organisms.

"The Relationship between Nucleus and Cytoplasm" again emphasizes the diversity of approaches to a subject which might at first sight appear to be more restricted. The twenty papers range from a study of truth and artefact in electron-micrographs of the nuclear membrane and the mitotic spindle (Lehmann), and of the various cytomembranes and their associated granules (Bernhard), through the fascinating story of the injection of ordered genetic material into bacteria during the mating process of *Escherichia coli* (Jacob), the results of the transfer of nuclei of different ages of embryo (Fischberg, Gurdon and Elsdale) and of different species (Moore) to enucleate ova, to studies of the different cytochemically distinguishable constituents of the nucleus during development and in different functional states of a wide variety of cells (Alfert). Other papers include one on the use of autoradiographs to determine the pattern of keratin synthesis in an epithelium by the use of sulphur-35-DL-cystine, in which there is some evidence that the nucleus is the first part of the cell to be involved (Pelc), another on their use in the synthesis of chromosome material (Ficq, Pavan and Brachet), and another on the use of chromatography to determine the patterns of amino-acids which develop in normal sea-urchin embryos and in those resulting from interspecific crosses. In the last, the amino-acid pattern is shown to be primarily maternal, even though paternal morphological characters may have appeared.

The dominant note which resounds from both symposia is that cellular behaviour and development result from a very intimate inter-relationship between nucleus, cytoplasm and environment, and that cells can no longer be regarded as being dominated entirely by nuclear influences.

E. N. WILLMER

Evaporation and Droplet Growth in Gaseous Media

By N. A. Fuchs. Translated from the Russian by J. M. Pratt. Edited by Dr. R. S. Bradley. Pp. vii+72. (London and New York: Pergamon Press, 1959.) 30*s*.; 5.50 dollars.

DROPLET evaporation in gaseous media is important in a wide range of problems such as the formation of cloud droplets, the evaporation of fuel in the internal combustion engines and in particular in fogs and atmospheric pollution. This book is a translation from a Russian paper by N. A. Fuchs, who himself has made most important contributions towards this subject. The treatment is largely mathematical, but a particularly valuable aspect of the work is the critical review of the whole of the experimental work in this field.

Fuchs considers evaporation and droplet growth in three chapters, of which the first is concerned with drops which are motionless with respect to the gaseous medium and thus no hydrodynamic factor is present. Chapter 2 deals with drops moving in relation to the gaseous medium—described as quasi-stationary evaporation—while the final chapter deals with non-stationary evaporation of drops in which the droplet is moving about in the gaseous medium.

In the first chapter, the basis of the theory is that put forward by Maxwell in an article on diffusion written in 1877 for the "Encyclopædia Britannica", and from this a rate of evaporation equation is developed. The influence of the Stefan flow on the rate of evaporation of drops is discussed, and also the influence of concentration change at the surface on the rate of evaporation. The fall in temperature is next considered both for freely evaporating drops and for supported evaporating drops with a very complete review of the experimental work.

As regards evaporation and the growth of drops moving relatively to the medium, Fuchs used the relationship which has been developed between the Sherwood and the Reynolds and Schmidt groups and discusses the effects of the diffusion and the rate-boundary layers.

F. H. GARNER

Boundary Problems in Differential Equations

Proceedings of a Symposium conducted by the Mathematics Research Center at the University of Wisconsin, Madison, April 20–22, 1959. Edited by Rudolph E. Langer. Pp. x+324. (Madison, Wisc.: University of Wisconsin Press, 1960.) 4 dollars.

THE Mathematics Research Center of the United States Army, founded in 1957, is directed by Prof. R. E. Langer of the University of Wisconsin; it has its permanent home in a new building in the center of the campus of that University. The scientific staff of the Center, numbering about thirty, consists in the main of mathematicians (not all American citizens) on leave from other institutions, who are free to work in any fields they please, though they may be called on by the U.S. Army for professional advice.

The principal interests of the Center are in numerical analysis, statistics and probability, analysis and classical applied mathematics, operations analysis. To increase interest in these fields, the Center held a three-day symposium in 1958 on numerical approximation, another in 1959 on boundary problems in differential equations, and proposes to hold more on similar subjects. The papers read at the 1959 symposium are now available in book form. Because of the shortage of time, the field of discussion was restricted to boundary problems for ordinary and partial differential equations. Even though initial value problems were excluded, the field is very wide. The nineteen papers, six of which were given by visitors from Europe, differ greatly in outlook. Some deal with numerical methods, others are in the strict tradition of classical analysis; a few made use of the more modern approach using fixed-point theorems for operators on a topological space. While some of the work has been published in more detail elsewhere, the book is, nevertheless, a useful addition to the literature of differential equations.

E. T. COPSON

Topographical Anatomy of the Dog

By Dr. O. Charnock Bradley. Sixth edition, revised by Prof. Tom Grahame. Pp. xiv+332+21 plates. (Edinburgh and London: Oliver and Boyd, Ltd., 1959.) 36*s*. net.

THIS well-known book, now in its sixth edition has retained its essential character as a systematic guide to the dissection of the dog. The general plan consists of a description of the various anatomical regions, including short, easily followed, dissection instructions. Thereafter the spinal cord, brain and lymphatic system are described, and finally useful tables of arteries and cranial nerves are added. The nervous system has been elaborated in the present edition, and there is an excellent brief account of the autonomic system. The text is concise and easily followed, and there are numerous illustrations, many of which are in colour. There is also a considerable number of radiographic plates of high quality, including several excellent injected specimens.

Prof. Grahame has to be congratulated for successfully revising this work to meet the requirements of modern veterinary practice, and there is no doubt that it will retain its established position as an essential text-book and guide to dissection. The book is very well produced, and the publishers are also to be congratulated for the high quality of their work.

T. NICOL

Ecological Processes

By Dr. Alan Mozley. Pp. xi+68. (London: H. K. Lewis and Co., Ltd., 1959.) 9*s*. net.

THE title of this book somewhat belies its contents. Far from being a generalized account, it is concerned with a few specific ecological problems considered mainly in the light of their influence on molluscs. These problems include certain aspects of ecological succession, population ecology and animal movement. The length of the book (68 pages) gives a fair indication of the depth of treatment: the text is almost entirely descriptive. Various references to other works are included, but these are few in number and scarcely make up for the general superficiality of the writing. It is somewhat surprising to find that the splendid work of Goodhart, Cain and Sheppard on populations of *Cepaea* is not even mentioned.

All things considered, it is a little difficult to see what prompted the writing of this book. Nor does the author's final "conclusion" help to throw much light on the matter—"study the ecological organization of the community, then alter it. In other words, study the ecological processes, plot their course, and modify them as necessary".

W. H. DOWDESWELL

THE INTERNATIONAL CO-ORDINATION OF TIME SIGNALS AND STANDARD FREQUENCY TRANSMISSIONS

By DR. L. ESSEN, O.B.E., F.R.S.
National Physical Laboratory, Teddington, Middlesex

IT was announced recently that plans have been made to co-ordinate the time-signals and standard frequencies transmitted in the United Kingdom and the United States. Such co-ordination has become possible as a result of the steady and remarkable developments in the precision of time-keeping which have taken place during the past decade. A recapitulation of these developments will show how co-ordination has now become possible and why it will be advantageous.

Observatory Time Signals

Time signals have been transmitted from powerful radio stations for more than thirty years. The Royal Greenwich Observatory signals, for example, are transmitted from Rugby on a number of wave-lengths. They consist of a five-minute series of seconds dots from 0955 to 1000 G.M.T. and from 1755 to 1800 G.M.T., the minute signals being lengthened for identification purposes. Such signals serve two functions. They give the time of day, which is a measure of the position of a point on the Earth's surface relative to the Sun, and also the unit of time, which is required for a wide field of physical measurements. The determination of time and the unit from astronomical measurements are complex processes. The observations need to be smoothed by means of clocks, such as quartz clocks, and many corrections have to be applied. The exact times represented by the signals can only be published in retrospect; the final values are to some extent an estimate, depending on personal judgment, and they are not necessarily the same for all observatories. Nevertheless, the unit of time has for many years been known to about 1 part in 10^8, or 0·001 sec. per day.

Standard Frequency Transmissions

Frequencies cannot easily be measured by means of the ordinary time signals. For example, if the seconds dots are accurate to 1 m.sec. it would be necessary to count vibrations for a whole day to obtain their frequency with an accuracy of 1 part in 10^8, which is the order of accuracy now required in the control of radio stations. Standards of frequency are therefore maintained in continuous operation and calibrated in terms of time signals extending over periods of months. Any other frequency can be measured in terms of the standard by simple techniques, which give a high precision in a short time. For example, two frequencies of nominal value 10^6 c./s. but differing by 1 c./s. can be compared with a precision of 1 part in 10^8 in a measurement time of a few seconds.

Standards of frequency have become elaborate pieces of equipment requiring careful maintenance, and there are therefore good grounds for making them serve a wide area by means of radio transmissions. Experimental transmissions were made in both Great Britain and the United States in the period between 1920 and 1930, and at the International Telecommunications Conference in 1947 the frequencies 2·5, 5, 10, 15, 20, and 25 Mc./s. were allocated to standard frequency services. There are now a number of continuous programmes of transmissions on some of these frequencies, the best known of which are those from Beltesville (near Washington, D.C.), having the call sign *WWV*, and from Rugby, having the call sign *MSF*. Such transmissions have been actively encouraged by the International Union of Scientific Radio with the ultimate object of giving a well-received signal anywhere in the world at any time.

The carrier frequencies are controlled by a standard of frequency and various modulation tones are added. It is generally found that the most useful of these are the 1-sec. timing pulses consisting of 5 cycles of a 1,000 c./s. tone obtained by dividing the frequency of the standard. The seconds intervals thus represent 10^6 cycles of the standard (when as in Britain it consists of a 10^6 c./s. quartz oscillator) and they can under good conditions be read with a precision of 10 μsec.

Doppler Effects and Very Low Frequency Transmissions

The full accuracy of the transmissions in the allocated high-frequency bands is obtained only in the small areas near the transmitters where the ground wave is received. At greater distances, where the wave is received after reflexion from the ionosphere, the received frequency may differ from the transmitted frequency by as much as several parts in 10^7 owing to Doppler effect changes caused by movements of the reflecting layers[1]. The effects are particularly severe at sunrise and sunset, and are least when there is a complete daylight path between the transmitter and receiver.

It is known that the propagation conditions for very low frequencies are relatively stable, and a transmission of 60 kc./s. was added to the *MSF* (Rugby) programme in 1951. In early measurements it was shown to have a stability of ±2 parts in 10^9 at Teddington (distance 120 km.), and Pierce[2] later estimated that the average frequency for the whole transmission period of 1 hr. was accurate to ±3 parts in 10^{10} at Cambridge, Mass., U.S.A. (distance 5,200 km.).

In view of these encouraging results, the Post Office Engineering Department controlled the carrier frequency of the powerful *GBR* 16 kc./s. transmitter from the quartz oscillator used for the *MSF* transmissions, and the signals received from this station have been studied in detail by Pierce[3]. He concluded that the Doppler shifts at sunset and sunrise were about 2 parts in 10^9, and that in the daytime the mean

Doppler shift is probably less than 1 part in 10^{10}. Somewhat greater Doppler shifts were, however, found with this transmission received in New Zealand.

At the beginning of 1960, a stable very low frequency transmitter was put into operation by the United States. This is a station at Summit in the Canal Zone with the call sign *NBA* and a frequency of 18 kc./s. Precision measurements can now be made, therefore, on signals crossing the Atlantic from west to east as well as from east to west.

The Atomic Clock

The high accuracies achieved over great distances using very low frequency transmissions were at first only accuracies of comparison, absolute values being limited by the uncertainty of the value of the unit of time. This situation was changed by the introduction of the atomic clock[4,5], which enabled frequency and time intervals to be determined and made immediately available with an accuracy of ±2 parts in 10^{10}. It thus became possible to express frequency and time directly in terms of an atomic constant. It is obviously important to ascribe a value to this constant which makes the units of atomic and astronomical time agree. The variations of the mean solar second (or, more precisely, the unit of the time system U.T.2) are, however, more than a hundred times greater than the accuracy already achieved with the atomic standard, and a more important relationship is therefore that between the atomic standard and the second of Ephemeris Time[6,7]. This has been determined by a joint programme[8] between the U.S. Naval Observatory and the National Physical Laboratory extending over three years, and the value for the cæsium F, m (4,0) $\rightleftharpoons$ F, m (3,0) resonance at zero field is 9 192 631 770 ± 20 c./s. The cæsium standard can be used with the precision of ±2 c./s. and the above value of frequency with these closer limits is being used as a unit of atomic time, although a value must ultimately be adopted by international agreement. Corrections for time signals in terms of a scale of atomic time have been published by the U.S. Naval Observatory since January 1957.

Co-ordination of Time and Frequency Services

As we have seen, the two kinds of service were developed independently to serve different purposes, but the 1 c./s. pulses on the standard frequency services became increasingly used as time signals and the times of the leading edge of the pulse in terms of U.T.2 were therefore published by the observatories. There were thus in the United Kingdom, for example, two systems of time signals in operation, and it would clearly be advantageous to the user if they could be co-ordinated. Such co-ordination, however, presented some difficulties because the second of Ephemeris Time, on which the frequency transmissions are based, differs considerably from the unit of the scale of uniform time (U.T.2), on which the time signals are based. This problem was discussed at the General Assembly of the International Astronomical Union at Moscow in 1958, and a method suggested there was put into operation on *MSF* (Rugby) in April 1959 (ref. 9). The frequency was offset by −170 parts in 10^{10}, the difference between Ephemeris Time and U.T.2 during 1958. Since the offset was previously announced, it presented no inconvenience to those wanting the time intervals in Ephemeris Time, or atomic time, and the 1 c./s pulses remained fairly close to U.T.2.

The co-ordination was taken a stage further in April 1959 through the co-operation of the Royal Greenwich Observatory, the Post Office Engineering Department, and the National Physical Laboratory[10]. The 1 c./s. pulses from the *MSF* quartz standard are now used to generate the Observatory time signals, so that all the signals from the United Kingdom mark identical intervals of time and, apart from the slightly different delay times in the control circuits, are accurately in synchronism. If the difference between the units of Ephemeris Time and U.T.2 is not equal to the predicted value, there will be a cumulative deviation from U.T.2 of the time pulses on all the services. These deviations will be removed by a step adjustment of 50 m.sec. made at 0000 G.M.T. on the first of the month. It is not anticipated that there will be more than one or two such adjustments per annum, and they can easily be taken into account in the determination of atomic time.

Similar steps have been taken to co-ordinate the time and frequency services in the United States[11].

International Co-ordination

It would be a great convenience to users if there could be a single service having a world-wide coverage; but although this is approached by stations such as *GBR*, the highest precision is obtained only when there is a daylight path between the transmitter and the receiver. A number of stations spaced at, say, 120 degrees of longitude around the Earth and all having exactly the same frequency and sending 1 c./s. pulses with a fixed phase relationship would resemble a single station and would overcome the Doppler effect at sunrise and sunset.

If the controlling standards are governed by a cæsium atomic standard, it should ultimately be possible to ensure that the frequencies are equal to within ±1 part in 10^{10}, but at present they may differ by a few parts in 10^{10}. The authorities in the United Kingdom and the United States will remove any such difference by mutual agreement.

The propagation time of the time signals makes it impossible to synchronize them at every point. It has been agreed, however, that the times of emission should be the same. If, for example, a step adjustment is found to be necessary, it will be made at an agreed time and by the same amount.

The experimental co-ordination now in progress will reveal any small residual propagation errors and give valuable information on the feasibility of providing time and frequency services which can be utilized throughout the world without the application of subsequent corrections.

THE NATIONAL PHYSICAL LABORATORY

THE work of the National Physical Laboratory, on show to visitors from industry, the universities and Government departments during May 25–26, covered a wide field in basic, chemical and engineering physics, metallurgy and mathematics. Items of both fundamental and applied research in all these branches were displayed.

The Laboratory is best known for its work in establishing and maintaining the fundamental British standards of various physical quantities, but in fact this only accounts for a small proportion of the total effort, and much of the work of the nine scientific Divisions is concerned with basic research on topics of immediate or potential value to industry.

The subject of noise measurement, for example, is becoming of public importance, and in the Applied Physics Division the problem of predicting the relative annoyance of sounds to the average listener is being tackled. For traffic noise a sound-level meter, using a microphone, amplifier and output meter, and with the subjective aspect covered by a frequency weighting arrangement, is likely to be the subject of an international agreement. Such a method is, however, a compromise between accuracy and expediency. Work at the National Physical Laboratory shows that the meter agrees with subjective measurements only within a restricted frequency-range. Subjective records of aircraft noise, made at last year's Farnborough Air Show, showed that for a given loudness a large number of observers judged a jet plane to be more disturbing than a piston-engined machine. This result could only have been predicted by a method of sound analysis requiring a number of different noise groupings, and therefore too elaborate for general practical testing. Work is also in progress to establish an International Standard for the normal threshold of hearing, the first necessity being an agreed design for a pure-tone audiometer.

In most fields the aim of research is to eliminate the subjective judgment, and in the Autonomics Division an interesting exhibit on the mechanical recognition of printed characters was shown. Previous systems for doing this have relied on a comparison of the specimen with ideal letter forms. In the exhibit, however, the degree of register between the unknown and its own image is continuously measured (*a*) in a rotary, and (*b*) in a transverse scan, by a light-transmission system. The output from a photocell then gives a characteristic wave-form for each character.

The possibility of an ultra high-speed computer is dependent upon reducing the switching-time in the individual elements, and work on cryotrons at liquid-helium temperature was shown. These devices depend on the difference in temperatures at which two metallic elements, in this case lead and tin, become superconducting. The magnetic field set up by a current through one of them restores resistivity in the other. Switching times as low as 10^{-8} sec. have been recorded. The devices are prepared by metal evaporation as in printed circuit techniques, silicon monoxide being laid down for intermediate insulating layers. The main problem is to achieve reproducibility in performance for large numbers of a single design. A possible computer element embodying about 170 cryotrons on a sheet 5 in. × 2¼ in. was shown.

Operation of the Laboratory's existing computer facilities, *Ace* and *Deuce*, is in the hands of the Mathematics Division, and several excellent examples of fruitful collaboration with other Divisions were displayed. For example, a statistical analysis of performance and design data from trawlers at sea, collected by the Ship Division, has been made on *Deuce*. As a result, six parameters have been defined, from which it is possible to predict the effective horse-power-speed curve for a given design. Trawlers have already been built incorporating improvements indicated by these same parameters, and these have shown outstanding rough-weather performance. In a similar way, improvements of 10–20 per cent in resistance have been obtained in the case of models. Computer work is also being done on curve-fitting to the hull surface of a ship, with the view of eliminating the full-scale fairing of a ship's lines on the mould loft floor.

The behaviour of ships in rough sea conditions is also being studied in a 100-ft.^{2} sea-keeping basin at the new Ship Hydrodynamics Laboratory at Feltham. A 10-ft. radio-controlled model of a trawler design was shown in operation at speeds up to 10 ft. per sec. in a wave system from a wave-maker along one side of the basin. Ultimately, it is intended to fit a transverse wave-maker for the generation of confused sea states. The model makes simultaneous records—film or digital—of roll, pitch, heave, torque, time, thrust, shaft speed, helm and heading. At the same time, the position of the model is fixed by means of an ultrasonic pulse, which by time of transit gives a bearing to three shore stations.

The Aerodynamics Division, in addition to fundamental work on high-speed flight, also devotes a considerable effort to industrial aerodynamics, and a low-speed wind tunnel, with 7-ft.^{2} section and a balance for simultaneous measurement of pitching, rolling and yawing, has been converted for such tests. The phenomenon of 'vortex shedding' can, at particular wind velocities, lead to dangerous oscillations of structures, and models of two tall chimneys were shown in an airstream. One of these was fitted with three helical strakes and the oscillation was shown to be eliminated. A similar type of problem is the oscillation of banks of parallel tubes such as heat exchanger tubes in a high-velocity gas stream. By means of films of a scale model of such a bank, studies have been made of the nature of the oscillation and its relation to various parameters.

A model of a single span of the proposed Severn suspension bridge was shown under test. The design is one of several possible ones which are being tested for compatibility between simplicity of construction and aerodynamic stability. The model itself is rigid, but on a damped free suspension, and is scaled for mass and inertia (1 : 48) and also for the frequency ratio of vertical to torsional oscillation. Under these conditions the air-speed at which oscillations occur is directly related to the air-speed at which they

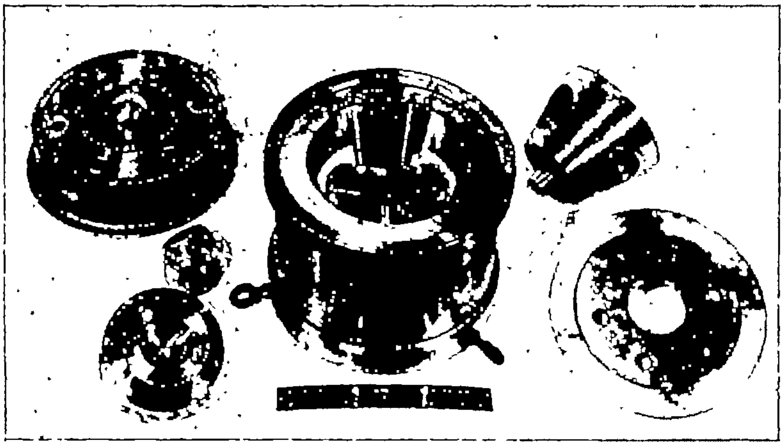

Fig. 1. Ultra high-pressure apparatus. This photograph shows the construction of the apparatus used to generate ultra high-pressures. The upper anvil is removed and the tetrahedral chamber is exposed. Crown copyright reserved

occur in the model. The latter has, in fact, been found to be stable at speeds up to 80 ft. per sec., corresponding to actual wind-speeds of 100 m.p.h.

The work in the Metallurgy Division on the fundamental mechanism of brittle cleavage fracture in single crystals of iron has been followed up by studies of the effect of orientation on the mechanical properties of polycrystalline iron. At right angles to the direction of plastic flow in rolling, the metal is not only brittle at room temperature, but also becomes progressively weaker as the temperature is lowered. This behaviour is not directly explicable in terms of the orientation effects in single crystals. The dislocation pattern of such cold-worked iron is being investigated by the examination of thin films on the electron microscope.

Brittleness in antimony–copper alloys has been connected experimentally with the presence of surface layers of high antimony concentration. The latter have been demonstrated by radioactivation, followed by the removal of successive 500-Å. layers with emery. After three such treatments both the surface composition and the mechanical properties of the metal correspond with those of the bulk material. After heat treatment for 20 hr. at 950° C., brittleness and the presence of one-third of a monolayer of antimony at the surface are restored.

Nuclear magnetic and electron-spin resonance are being used for studies of the fundamental properties of materials, particularly polymers, in the Basic Physics Division. Preliminary work on solids at extremely high pressures has been carried out in an apparatus consisting of a tetrahedral arrangement of four tungsten carbide anvils (Fig. 1) subjected to hydraulic pressure (200 tons load). The centre tetrahedron (side-length 0·75 in.) of pyrophyllite, which transmits the pressure hydrostatically to the specimen (0·3 in. × 0·1 in. diam.), can be seen dismantled in Fig. 2. Connexions for measuring resistance, temperature, or for heating the specimen, are made via the anvils. In preliminary work pressures of 77,000 atm. have been attained, as shown by observation of the resistivity transition point of barium metal. With the apparatus it is intended to study the effect of pressure on the properties of semiconductors.

For pressures of more normal industrial interest, in the 5–10,000 atm. region, pressure balances have been calibrated to a few parts in 100,000. The correction to be applied for elastic deformation of the piston–cylinder assembly has been determined by measurements with two assemblies of materials of different elastic constants (steel and aluminium bronze) in opposition, and also by determining the rate of flow of liquid between piston and cylinder at different pressures. The two methods give very closely agreeing results. This work will also be used to study the crystal and electronic transitions of the various elements under pressure.

Engineering requirements have always been prominent in the programme of the Standards Division. A 450 tonf. secondary standard load cell incorporates nine 50 tonf. struts, each of which is calibrated on a deadweight machine. Each strut has eight strain gauges connected in pairs to bridge circuits, the outputs from which are fed to a digital recording circuit capable of an accuracy of ± 5 μV. in 2,500 μV.

The same Division, with its tradition of high-precision metrology, is well equipped for the construction of a new primary standard of mutual inductance, one of the two basic instruments for deriving electrical quantities from the fundamental units of length and time. The design follows the

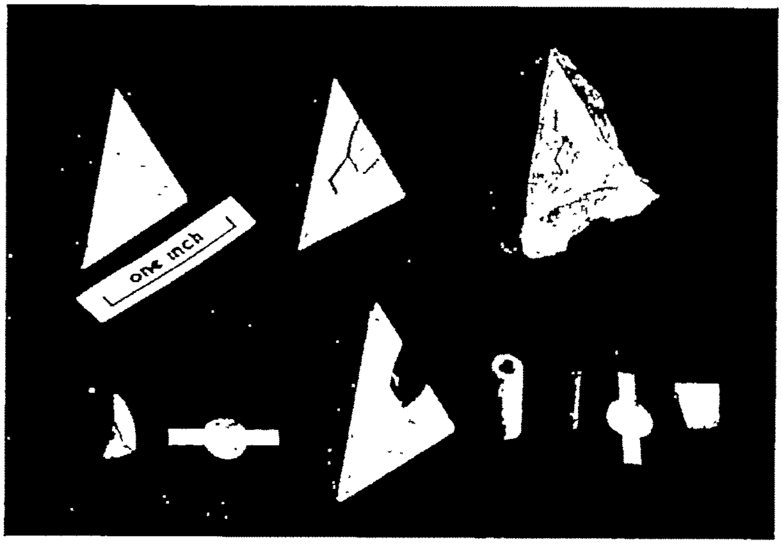

Fig. 2 Ultra high-pressure apparatus. This photograph shows samples of the pyrophyllite tetrahedra. At the upper right is one which has been loaded and shows the gasket formation; the lower position is an exploded view of the assembly and shows the test samples, the silver chloride sleeve, electrical contacts and the completing pieces of the pyrophyllite tetrahedon. Crown copyright reserved

original one of A. Campbell, with two coaxial helices, separated by a gap equal to their combined length, wound on a helical groove in a fused quartz former. A secondary of many turns is situated in a plane midway between the helices. With modern methods of metrology, including interferometric techniques for length, it is hoped to realize considerably greater accuracy in the dimensions of the complete assembly than in the earlier standard.

A new field in which there is a growing demand for a high precision is the measurement of temperatures in the region 10–90° K., and a helium gas thermometer used for such purposes was on show. The helium is contained in a constant volume, changes in pressure being measured as changes in capacity by movement of a thin metal diaphragm. Fixed points are the boiling points of oxygen (c. 90° K.) and hydrogen (c. 20° K.), and work is in progress to realize the triple point of oxygen (c. 54·4° K.). It is thus hoped to extend the International Temperature Scale below the present limit of 90° K. Platinum resistance thermometers, calibrated against the helium thermometer, have been compared with others from the National Bureau of Standards, Washington, and from Pennsylvania State University with an agreement between laboratories of ± 0·02° over the range 20–90° K.

In the Light Division an attempt is being made to establish an absolute standard of luminous intensity without reference to a black body radiator. The response of a photocell is calibrated in volts per watt of incident radiation in an absolute radiometer. The same photocell is then used to measure the output from a secondary standard lamp (2,042° K.), using a liquid filter designed to give, in combination with the photocell, the same relative spectral response as the standard photometric eye. The same experiment has also been carried out with a filter–thermopile combination (the lamp temperature being 2,854° K.). Values of 673 and 676 lumens per watt at 0·555μ were obtained. The theoretical figure, depending on the values accepted for various constants in the temperature scale, is within the range 670–686.

The foregoing are chosen from more than 170 topics on display, which in turn represented only a proportion of the wide range of the total programme of the Laboratory. H. G. Short

FINAL MONTHS AND DESCENT OF SATELLITE *SPUTNIK* 3

By B. R. MAY and D. E. SMITH

Radio Research Station, Department of Scientific and Industrial Research, Slough

NOW that the satellite *Sputnik* 3 has descended, it is possible to review the last months of this satellite's existence, which ended on April 6, and to outline the main features of its 692-days lifetime, in which it performed some 10,037 revolutions and travelled more than 280 million miles.

Previous articles[1,2] reviewed the satellite's progress up to the end of April 1959, and we may now show the mean nodal period–time curve from the beginning of May 1959 until its descent (Fig. 1). It follows generally the expected shape, the slope increasing steadily from about 1·0 sec./day on June 31, 1959, to 1·8 sec./day on October 31, and to 2·5 sec./day on January 31, 1960. Since the beginning of May 1959 the perigee moved (in a direction opposed to the orbital motion of the satellite) from southern apex towards the equator, where it was on January 11, 1960, and had reached nearly 40° N. when the satellite descended.

Table 1 gives the orbital elements for *Sputnik* 3 from June 1.00, 1959, to April 1.00, 1960, obtained in the same manner as before[1]. The calculations have been made for only one value of scale height instead of two, since more reliable values for the scale height at the perigee height (also included in Table 1) are now available.

The period–time curve for the complete lifetime of this satellite has been plotted in Fig. 2, and the variations in the slope of the curve indicate the constantly changing atmospheric density encountered by the satellite at its perigee. The shape of the curve is affected by the rotation of the orbit, and its departure from a regular form has created difficulties in producing predictions the accuracy of which is better than 2–3 min. at the end of a period of a week, and in estimating the date of descent of the satellite[3]. The curve also displays irregularities lasting only a few days—those which occurred during

Table 1. Orbital Elements for 1958 δ_2 (Figures in brackets are probable errors)

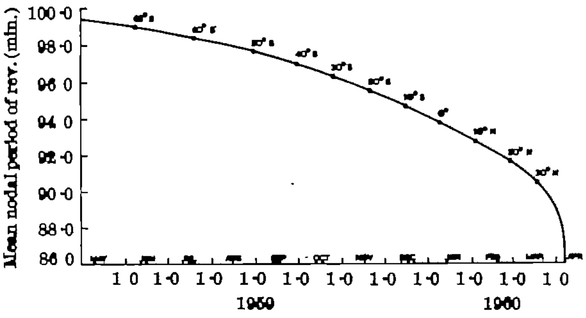

Fig. 1. Nodal period of revolution of Satellite 1958 δ_2 (*Sputnik 3*). Numbers on curve indicate latitude of perigee

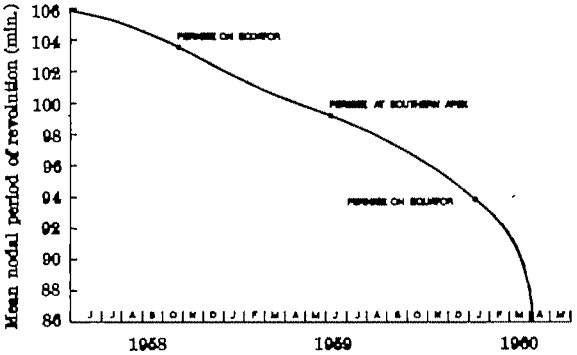

Fig. 2. Complete period–time curve for Satellite 1958 δ_2 (*Sputnik 3*)

July 15–19, August 17 and October 4–7, 1959, coincided with prominent geomagnetic storms on those dates.

The mean nodal period–time curve kept for prediction purposes, and which is accurate to 0·005 min. over the major part of the lifetime of the satellite, has been based upon optical and radio observations made mainly in the United Kingdom, Finland and France. As an object for visual observations the satellite was not very bright, and although the brightest magnitude reported was +1, the majority of observations were made at magnitudes of between +4 and +7. Due to this and the general irregularity of its brightness, the satellite was detectable only with difficulty with cameras and the more elaborate tracking instruments of small angular field, so that the majority of the 500 or so observations of time and position made in the United Kingdom were obtained by amateurs using quite modest instruments. The satellite's transmitter on 20 Mc./s. radiated during the whole of its lifetime, though after some three months it failed to transmit useful telemetry information, and from December 1959 there remained only a C.W. signal with spasmodic modulation. Since, at the time of its descent, the satellite was visible only from two narrow bands of latitudes situated near northern and southern apex, the radio transmissions provided the principal means of following its final revolutions.

Little is known about the descent of this satellite, as its suspected last transit lay mainly over the sea and unpopulated areas. The last reported visual sighting, at the time of writing, was made from Jokioinen in Finland at about 01.45 hr. U.T. on April 6, and it was unlikely that any later sighting would have been possible from consideration of the visibility conditions. Three transits later, the radio signals were picked up at Jodrell Bank, Berlin, Darmstadt and the Radio Research Station at Winkfield (where interferometer measurements were made) at about 06.11 hr.–06.15 hr. (position *A* in Fig. 3) and the last known positional radio observations were made on the following transit at about 07.30

from Prince Albert, Saskatchewan (position *B*), and at about 07.43 from Winkfield (position *C*). At 08.00 hr. the period appeared to be 86·8 ± 0·2 min. and from theoretical considerations the satellite would have a further lifetime of about 1–2 hr. Moreover, it has been reported that a short, faint signal at the correct frequency was heard at both Berlin and Winkfield at about 09.13 hr. (position *D* in Fig. 3), when the satellite was below the horizon from both stations. A normal half-hop transmission seems to be impossible from a consideration of the position of the satellite and its transmitting frequency, but it is possible that propagation by scattering in the ionosphere may have taken place rather than reflexion, since the ionosphere was very disturbed in this region at this time. This evidence must, however, be regarded as inconclusive.

We should like to take this opportunity of thanking all those who have sent us radio and optical observations of this satellite, thus enabling a regular flow of predictions to be maintained.

This work was carried out as part of the programme of the Radio Research Board and is published by permission of the Director of Radio Research of the Department of Scientific and Industrial Research.

SCIENTIFIC RESEARCH AND DEVELOPMENT: A COMPARATIVE STUDY

By S. DEDIJER

Formerly Director of the Boris Kidrich Institute of Nuclear Sciences, Belgrade

THE scientific potential of Yugoslavia and the effort to increase it are to-day much greater than in 1940. Nevertheless, many Yugoslav scientists have felt for years that their country was neglecting science and that a sounder and a more vigorous research policy was needed. Owing to a lack of liaison between the embryo scientific community and the State nothing was done to back up these impressions with quantitative evidence. This happened also because the Government felt, by what it calls now "the logic of development", that the country could not concentrate both on the development of science and industrial production potential. In the latter case considerable results have been achieved; outside observers consider the economic development of Yugoslavia to be to-day among the most rapid in the world. Lately, however, a new, previously lacking awareness of the consequences of the 'logical' neglect of research has begun to appear in Government circles. The following statement[1], the first such made by a Yugoslav Government and Communist League leader, perhaps best illustrates the background of the recent trend toward a more vigorous research policy:

"We have posed ourselves the goal to catch up economically and culturally with the developed countries of the world and to do it as rapidly and as soon as possible. But how to do it when the world is striding forward at great speed in the midst of a scientific–technological revolution? The forces of organized scientific–technological creativity are continuously and rapidly growing and the developed countries are in a position to introduce incessantly ever new and more abundant knowledge and to create new productive forces. Under such dynamically competitive conditions a country which develops its production only on the basis of the existing, routine technology cannot reach the same goal as the most developed countries. On the contrary, such a country will unavoidably and 'systematically' lag. . . . In this sense, we are lagging behind the most developed countries."

Whether one defines it by generalizing Marx's definition of work or by using the broader concepts of cybernetics, a research policy calls for decisions on: (1) The principal goals which a society can and should reach by means of its research potential. (2) The magnitude of the 'physical' elements of the scientific potential: personnel, equipment, finances, etc. (3) The long-range research programme, that is, the distribution of the scientific potential with respect to the main social goals. (4) Time distribution of the scientific effort. (5) The social and political measures needed to make the potential both scientifically and socially productive.

Until recently Yugoslavia had very little of the information needed to make sound decisions on any of the above components of a research policy. The tables in this paper were prepared in order to estimate and illustrate how much Yugoslavia is "lagging behind the developed countries". This is done by comparing the orders of magnitude of the scientific effort per inhabitant of Yugoslavia and its economic potential with those of the United Kingdom, the U.S.S.R. and the United States.

The tables, with the appropriate comments, served as an introduction to the discussion between the representatives of science, industry and Government at a symposium on the organization of research of the First Yugoslav Chemical Congress, held in Zagreb during June 15–21. Some of the tables, with added comments of a more general kind, are presented here.

Looking through the various national statistical yearbooks one is impressed by how many countries have felt the need to count their donkeys and how few their scientists. This is because many countries are just beginning to consider what the current scientific revolution means to them. But even countries which gave birth to the industrial and the scientific revolutions have begun only recently the difficult task of measuring the various aspects of the interaction of science and society. As late as 1957, for example, the Advisory Council on Scientific Policy of the United Kingdom[2] pointed out that "this is a field in which it is difficult to obtain precise and comprehensive statistics", regretted "that comparable figures were not available for Western European countries" and warned that "although we have to some extent followed the American model in the presentation of our statistics, any comparison should be made with considerable reserve".

To make a comprehensive comparison of the role of science in various countries one should take into account the scientific efforts, the scientific potentials and their social and scientific productivities. Yet for most of these concepts no one has devised up to now reliable measuring rods. In the case of Yugoslavia the small amount of data existing on research was based on ill-defined (if defined at all) concepts and on criteria generally unacceptable in comparison with those adopted in the developed countries. For all these reasons, the possible field of comparison was limited to a small number of research indicators on which the most elementary statistics exist in all the countries in question and to which a common set of criteria could be applied. This also limited the comparison to the year 1957. The indicators are:

(1) The annual expenditure on research and development. (2) The number of scientists and engineers. (3) The annual production of engineers and scientists. (4) The expenditure on research in various industries.

The necessity to limit ourselves to these indicators of the scientific effort and potential has biased the comparison in favour of Yugoslavia. For they do not tell us anything about the scientific and social productivity of the research policy. The countries with which we are comparing Yugoslavia's scientific effort and potential have had experience with research for tens and even for hundreds of years, and have been aware of the economic and social consequences of the scientific revolution much longer than Yugoslavia. Let us take, for example, one hundred young men entering a branch of research in one of the three developed countries and a hundred in Yugoslavia. The first hundred were trained in universities where research has a long tradition. They are only another hundred research workers becoming a part of an existing scientific potential with a long tradition. The hundred Yugoslavs come from over-crowded, under-staffed and under-equipped universities, where, everyone in Yugoslavia readily admits, research is neglected by tradition and until recently by policy. Most likely, they are the first hundred research workers in the given branch; and they are to work as a part of an embryo scientific community with many negative and few positive inherited traits. All this is not conducive to make the Yugoslav hundred into a highly productive nucleus in the given branch. Thus, were we to compare the results obtained from a given investment in research, the comparative picture would be much less favourable to Yugoslavia than the tables indicate.

To avoid the risk of under-estimating the scientific effort of Yugoslavia, the maximum figures and the most favourable variants were taken and the same criteria as in the developed countries were applied. Thus, in estimating the number of university teachers engaged in research, the same criteria were used as in the United States and the United Kingdom, although this is quite unrealistic. Also, whenever there was any doubt if a sum of money had already found its way into the "research expenditure of Yugoslavia", it was added anew rather than risk to omit it. Hence, the probability of the error in the Yugoslav figures on research being plus is equal to 0. The probable errors for the corresponding data for other countries are not given, simply because, with a single exception, the sources do not quote them. This, however, is not vital since we are only comparing the orders of magnitude of scientific efforts.

The general sources of all the data are given at the end without quoting them for each particular figure. The Soviet data on research expenditure were taken from Western sources.

Yugoslavia's lag in research in 1960 is probably greater than Table 1 shows for 1957. For, according to one estimate, except in nuclear energy, Yugoslavia is not spending more on research in 1960 than in 1957. The United States, on the other hand, has increased its expenditure in 1959 by about 50 per cent over 1957, while the U.S.S.R. has increased it in 1960 by 15·4 per cent over 1959 [3].

Table 1. EXPENDITURE ON RESEARCH AND DEVELOPMENT PER INHABITANT (1957)

	(American dollars)	(Relative)
United States	47·9	53·2
U.S.S.R.	26·5	29·4
United Kingdom	18·2	20·1
Yugoslavia	<0·9	1
British Colonies	0·05	1/18

To illustrate the dynamics of growth of the scientific effort we have chosen the United States (Table 2) because the statistical data are most easily available.

Table 2. DYNAMICS OF GROWTH OF THE SCIENTIFIC EFFORT (UNITED STATES)

Year	Electrical energy	Steel	Expenditure on research and development
1945	1·0	1·0	1·0
1950	1·4	1·2	1·8
1951	—	1·3	2·2
1952	—	1·2	2·5
1953	—	1·5	2·6
1954	—	1·1	2·7
1955	2·3	1·5	3·6
1956	—	1·5	4·3
1957	2·6	1·4	5·4
1958	2·7	1·1	6·6
1959	—	—	8·2

Table 3 is least satisfactory from the point of view of method. It has been assumed that what in Yugoslavia is called 'social product' and 'national economy investment' corresponds to the gross national product and fixed capital formation used in the United States and the United Kingdom. Some Yugoslav economists estimate that the gross national product is by definition about 10 per cent greater than the 'social product'. If we actually used the gross national product, the figure 0·5 per cent for Yugoslavia would be even smaller. The Soviet figures were obtained from ref. 4.

It would have been illuminating if the tables contained data from countries equally or less economically developed than Yugoslavia. It is significant, although unfortunate, that such material seems scarcely to exist in the published literature—if at

Table 3. PORTION OF GROSS NATIONAL PRODUCT SPENT ON RESEARCH AND DEVELOPMENT AND GROSS FIXED CAPITAL FORMATION (1957)

	Research and development expenditure as per cent gross national product	Fixed capital formation as per cent gross national product
Yugoslavia	<0·5	27·5
U.S.S.R.	2·1(?)	15·0(?)
United Kingdom	1·7	15·5
United States	1·9	17·4

Table 4. COMPARISON OF THE ECONOMIC DEVELOPMENT AND SCIENTIFIC EFFORT PER INHABITANT (1957) (RELATIVE)

Country	Electrical energy	Total energy	Steel	Sulph. acid	Cement	Shoes	Dollars for science
Yugoslavia	1	1	1	1	1	1	1
U.S.S.R.	3·1	4·2	4·4	3·3	1·3	1·4	20·4
United Kingdom	5·2	8·1	7·2	6·7	2·1	2·5	20·1
United States	12·2	14·8	10·3	12·8	2·8	3·1	53·2

Table 5. SCIENTISTS AND ENGINEERS PER INHABITANT (1957) (RELATIVE)

Country	Scientists, engineers in research	Engineers in industry	Graduating Engineers	Graduating Scientists
Yugoslavia	1	1	1	1
U.S.S.R.	5·5	11·1	5·7	1·8
United Kingdom	4·0	3·6	1·9	3·3
United States	7·1	8·3	2·5	5·9

all. For this reason in writing about the undeveloped countries, as one author has said, one is prone to commit the well-known sin of over-generalization and under-documentation. This sin of 'feigning hypotheses' will not be avoided in the comments to the tables.

Whether there is a general 'logic of development' which makes undeveloped countries neglect research, as evidently Yugoslavia has done up to now, is difficult to say. But some of the few economists who have considered the role of research in economic development seem to agree that "There is no doubt that one of the main deficiencies of underdeveloped countries is their failure to spend adequately upon research and upon the development of new processes and materials appropriate to their circumstances"[5]. From Table 3 and the available inadequate, partial evidence from other countries, one could reformulate W. A. Lewis's words as a quantitative 'law': "The higher the economic development of a country, the greater is the percentage of the gross national product invested in research".

This 'law' actually represents a new definition of an undeveloped country in the scientific revolution era. It would be worth while to analyse the causes of this 'law' by all the methods available to social science. Here we shall only point out some of the consequences of such neglect of research.

As Marx would have put it, research lowers the 'exchange value' and increases the 'use value' of the existing goods; it creates completely new 'use values' by creating new products for new needs. Thus, for example, in the United States, "about 41 per cent of the manufacturing industries research money is spent on the improvement of present products, 48 per cent on new products and only 11 per cent on new processes"[6]. Research increases the productivity of labour; according to one source[7] almost 1 per cent of the annual increase of productivity of labour of 2·2 per cent in the United States is due to research. By neglecting research an undeveloped country has to leave it to others to transform its raw or semi-fabricated materials into new or better kinds of products, which it will have to buy. At the same time, it will continue to spend more labour per unit product than the countries which encourage research. Thus it continues to be an object of exploitation in the world market.

To cope with the "dynamically competitive conditions" of the scientific revolution mentioned by Mr. Popovich, a country must start to develop research simultaneously with its economic potential. For although research expenditure constitutes a small percentage of the gross national product, it takes considerable time to translate it into tangible results. To transform a laboratory result into an economically successful commodity takes on the average 5–10 years. It takes at least 10 years to train a talented secondary school graduate for research. The time needed to create 'tradition', that is, the atmosphere necessary for productive scientific work, is much longer. It follows that the results of neglecting research will be felt only when it may prove too late to cope under competitive conditions.

Some of the noticeable characteristic traits of science in undeveloped countries can be attributed to the neglect of research; such as, for example, the neglect of research in the universities. From the official figures on research expenditure in the universities, one can conclude that Yugoslavia spends not much more than 1 per cent of its research funds there. This is several times less than in the United States and the United Kingdom. At the same time that the universities are starving for research funds, the research institutes are thriving. That Yugoslavia is not alone in this is shown by the following resolution of the physics teachers of India[8]: "As the main burden of training future physicists must be borne by the universities, the Universities Grant Commission is requested to ensure that the emoluments, research grants and other facilities available to the universities teachers are adequate and in no ways inferior to those available to people in similar positions in the National laboratories or elsewhere". There is evidence that scientists in Yugoslavia and India are not alone in feeling this way.

In listing a set of decisions constituting a research policy, perhaps the most important was put last. This can be seen from the following words of Prof. Polanyi in *Science* in 1950, illustrating something encountered by anyone who has studied this or that phase of developing science in one or several new countries.

"Those who have been in those parts of the world where the life of science is just beginning, know the tremendous difficulties and the struggle which the lack of scientific tradition imposes upon the pioneers working to found science in these countries. On one hand the research work is stagnating because of lack of encouragement, and on the other it is developing completely chaotically for the lack of any kind of directing influence. Unsound reputations spring up like mushrooms, founded on nothing or on the commonest results, or often on empty boasting. The political and economic interests influence to a large extent the nominations to important positions and in deciding on funds for research. No matter how great is the local talent, such an environment will not make it possible for it to develop" (translated from Yugoslav).

This illustrates only some of the aspects of a lack of transfer of information inside a research community and between it and the other sectors of society, such as industry, Government and others, which must participate in formulating a research policy. Such a lack of information, among other matters, gives rise to the 'nuclear myth', so prevalent in undeveloped countries. There is a fair amount of qualitative evidence that in some of these countries the expenditure on nuclear physics and nuclear energy research is many times greater than in the fields of utmost economic importance. In the case of Yugoslavia there is also quantitative evidence. Thus, for example, from Table 6 presented at the symposium (not published here) one can estimate that in the next five years Yugoslavia now plans to spend about ten times more on research in nuclear energy than in the chemical, metal, petroleum, food, textile, paper and non-metal industries combined, which in 1958 contributed 22·5 per cent of its national income. This should be considered in the light of the statement of a Nuclear Energy Commission spokesman that Yugoslavia will need nuclear power at the earliest 20–25 years from now[9].

"Science is the motor of social progress", said one of the slogans at the fifth Congress of the Socialist League of Yugoslavia, its mass political organization, in May 1960. The logic which neglects the development of a sound research policy results in the development of all parts of the vehicle of social progress except one: its motor. From all that has been said it emerges that the usual economic indicators are necessary but not sufficient as a measure of economic development. Any measurement of economic development to be adequate must include indicators about this motor, that is, about the scientific effort, the scientific potential and its scientific and social productivity.

MEASURING THE SIZE OF ISOLATED CELLS

By DR. SAMUEL S. EPSTEIN and JACQUELINE B. WEISS
Hospital for Sick Children, Great Ormond Street, London, W.C.1

THE accurate sizing of individual cells is a problem which has interested microscopists since the seventeenth century. One of the earliest recorded attempts at measuring the size of cells was made by Leeuwenhoek[1] in 1684. He selected grains of sand of similar size, arranged them along graduated lines and determined the number of grains to the inch. He then attempted to size red blood cells by relating their diameters to a grain of such sand. An equally ingenious approach was that of Jurin[2], who in 1718 twisted hair finely around a pin and measured microscopically the length of a coil and the number of component twists, thus obtaining the diameter of the hair. He then counted the number of red cells which equalled the diameter of a segment of hair.

With the progress of optical science and microscope design, projected cell images were measured by means of an ocular prism attachment (camera lucida). No real degree of precision, however, was reached until 1910 when Price-Jones[3] described his classical method for determining variations in the diameters of red blood corpuscles. He projected the images of microscopic fields of stained blood films directly on to paper in a system of known magnification. Individual cells were outlined in pencil, measured with a millimetre scale and their diameters expressed in μ. The average diameters of successive groups of 100 cells were found to be relatively constant. This procedure was afterwards refined when Price-Jones[4], applying the statistical concept of Yule[5], plotted size distribution curves of groups of 500 red blood corpuscles. He also suggested methods for the measurement of non-circular cells, based on the assumption that the average of their greater and smaller axes approximated to the circular diameter.

In 1924, Pijper[6] demonstrated that red blood cells spread in a monolayer on a glass slide would function as a diffraction grating—the translucent interspaces allowing passage of unaltered light. Diffraction would thus occur at the edge of each cell. This same observation had, in fact, been made a century previously by Young[7], who devised an 'eriometer' to measure size of wool fibres and later adapted this to red blood cells. A source of illumination, viewed through such a slide as Pijper described, appeared surrounded by a series of concentric halo spectra, the size of the halo being inversely proportional to the size of the cell. This method is of limited value when there is much anisocytosis, as it determines the modal rather than the arithmetic mean. Furthermore, it is strictly applicable only to cells which are both circular and translucent.

Measuring the approximate size of bacteria was performed in 1926 by Wilson[8], who related opacities to cell counts of suspensions of organisms. Earlier, Brown[9] had related the dried weight of organisms to their opacity in suspension. At this time bacteriologists on the whole were not interested in determining the size of bacteria—accepting the doctrine of Koch that cell forms are invariably constant. However, in 1928, Henrici[10], in a monograph on problems of morphological variations of bacteria, described in detail several methods for measuring the size of micro-organisms. For rod-shaped organisms he applied the type of projection method described by Price-Jones, and expressed cell size as a function of length. He also made size-distribution studies at different phases of growth, in this respect preceding Price-Jones's concept that determinations of average cell size alone were of limited value. With curved organisms, such as *Vibrio cholera*, he re-photographed the pencilled cell images as composite photographs, arranging the organisms in such a way that the centres and long axis of each separate cell coincided as nearly as possible on the plate. He measured cell area with a planimeter and length with dividers and derived an area/length index distribution curve for each stage of growth. For very small organisms he devised a method designed to overcome the difficulties of projection at high magnifications: projecting the cell images on to panchromatic films at a magnification of 3,000 times and reprojecting these photomicrographs at a magnification of 7–10 times. The projected images were traced on to cards and their area and length measured. Henrici found that by counting a sufficient but unspecified number of cells, the error due to fuzziness at the edge of the projected images could be compensated. He did this by tracing through the centre of the "zone of unsharpness", the chances being as great for "going inside the middle of this zone as outside of it". More recently an original technique, based on comparative weights of paper cut-outs of projected cell images, has been applied to a microbiological system[11].

Ocular Graticules

In recent years measuring the size of particles has attracted the attention of physicists and in the course of the past decade two distinct approaches to this problem have been evolved: the visual and the automatic. Strictly visual methods of measuring the size of particles applicable to cells involve the use of eye-piece graticules. These constitute a modification of the micrometer described more than a century previously by Kater[12], whereby a scale seen with the left eye was superimposed on cell images seen with the right eye. The more recent methods consist essentially of graticules with rectangular grids defining the counting area and a series of reference circles in the grid by which images are visually matched[13,14]. Other methods of reference include graticules with vertical lines of known separation[15], and gauges such as the flocytometer. Statistically designed techniques employing particle profile test strips have been used to assess the accuracy of graticule methods and minimize observer bias[16].

Spot Scanning

In general, automatic devices have depended on the use of television techniques and the photo-electric spot scanning of a specimen, either directly from a microscope preparation or from a photograph which can be taken from living material[17,18]. These methods are capable of providing rapid information and enable the analysis of numerous replicates. Several principles of spot scanning have been applied; these include double scanning, which compares counts obtained by scanning at different track widths, and intercept length scanning, whereby the number and length of intercepts of scanning lines across particles are measured and area and perimeter of the particle deduced. The guard spot method is a refinement of the intercept method and involves the use of two scanning spots, one controlling counting of the other. The absence of the control signal indicates that the lower or upper edge of a scanned particle has been reached. Thus a count of one is registered for each particle. Information from such a scanning analyser can be obtained in three forms: total count, mean area and approximate size distribution of particles or cells.

Certain errors may be introduced in both counting and estimating size by the aggregation of cells and, furthermore, irregularly shaped cells may be counted more than once due to re-entry of the counting spot. Information in the case of these cells may best be derived from their mean area in a given field by the integration of total cell area and count. Size distribution analyses are not easily performed. With circular cells, size is generally expressed in terms of diameter, and measuring size can be performed by counting only cells the diameters of which exceed a selected length. A distribution analysis of the complete field can therefore be obtained by counting at consecutive size increments—the value of the increments being determined by the field size. Where small size increments, such as those for red blood cells, are required, distribution curves cannot be obtained at a useful magnification on conventional machines. In general, the minimum measurable increment is of the order of 1·5–2μ in a field of $300\mu^2$.

The flying-spot particle resolver, which uses an electronic memory-device to simulate the double scanning spot, has been used for the determination of the mean area of *Euglena gracilis* grown at various concentrations of vitamin B_{12} (ref. 19).

Double-Image Microscopy

A semi-automatic visual method of determining the size of a cell—a double-image microscope micrometer—has recently been described[20,21]. This consists essentially of a mirror mounted on the diaphragm of a loudspeaker-type transducer, which is introduced between objective and eye-piece in a simple microscope system. The transducer is fed with alternating current, and the light source is arranged to flash when the vibrating mirror is at extreme positions. As a result of persistence of vision, two stationary images of each particle are seen. Image separation, in a vertical direction, depends on the amplitude of current and can be varied by means of a potentiometer. The diameter of a circular cell can thus be recorded on a calibrated ammeter after image separation has been adjusted so that the two images just touch. With irregular particles the microscope stage is rotated so that any chosen chord of the particle may be measured in the same manner. The reproducibility of this method for measuring circles is better than 1 per cent at 10μ and 3 per cent at 1μ. The instrument can be fitted with an electromagnetic device[22] for size distribution analyses. A more tedious modification involving the same principle in which, however, the image is split by shearing with two prism blocks arranged as an interferometer has also been described[23].

Cell Conductivity

The methods so far described are only capable of evaluating optical cross-sections of cells. A machine has, however, been devised (Coulter Electronics, Chicago) for the automatic measurement of cell volume[24,25]. This method depends on differences in resistance between cells and the fluid medium in which they are suspended. The cell suspension is forced through a small aperture of appropriate width, which has an immersed electrode on either side. Each cell, as it passes through the aperture, causes a change in resistance between the electrodes. A voltage pulse of short duration is thus produced which has a magnitude proportional to the size of the particle and which is essentially proportional to particle volume. The voltage pulses are amplified, fed to a threshold circuit with an adjustable threshold-level and counted. By counting at successive threshold increments, size distribution curves can be easily and accurately obtained. Corrections are automatically made for co-incident passage of more than one particle through the aperture, and the large number of particles counted minimizes error. Calibration is performed by using standard particles of known size. The accuracy of this method as applied to measuring the size of bacteria has been shown to be of the order of 2 per cent of the diameter for 1μ spheres[26]. It will be obvious that information obtained from a machine of this nature is of greater potential value to biologists than more conventional methods merely measuring some planar function.

NEWS and VIEWS

Electrical Engineering in the Imperial College of Science and Technology

Sir Willis Jackson, director of research and education with Metropolitan-Vickers Electrical Co., Ltd., now the Associated Electrical Industries, Ltd., and president of the Institution of Electrical Engineers, has been appointed to the chair of electrical engineering at the Imperial College of Science and Technology, London. He will take up this post in October 1961, succeeding Prof. Arnold Tustin, who has been responsible for the central planning of the new building for the Department, and who has for some time wished to relinquish the post of head of the Department. Prof. Tustin will continue to direct the work of the Department in the field of heavy electrical engineering. Other leading members of the Department are Prof. Dennis Gabor (applied electron physics) and Prof. Colin Cherry (telecommunications).

The new appointment exemplifies the very close links which now exist between industry and the Imperial College at the highest level. Sir Willis Jackson resigned his chair at the College some seven years ago to go to Metropolitan-Vickers (see *Nature*, 171, 242; 1953). From this position he has exercised great influence both within the electrical industry and in the field of technological education in general. Now he is to return to his old College and his old Department. It is of the highest significance that one of the most distinguished technologists in Britain should be re-entering the academic ranks in a key post.

Royal Society Visiting Professorship: Prof. A. Schlüter

The Royal Society has instituted a visiting professorship so that overseas scientists of high distinction may be invited to the United Kingdom for a period of an academic year, or at least six months, to enable them to carry out research. The first holder of the appointment will be Prof. Arnulf Schlüter, professor af theoretical physics in the University of Munich, and also of the Max-Planck-Institut fur Physik und Astrophysik, Munich. He will take up the appointment on March 1, 1961, and work in the Department of Applied Mathematics and Theoretical Physics at Cambridge on problems in theoretical astrophysics and plasma physics. Prof. Schlüter, although still a young man, has achieved international distinction for his work. He was among the first to perceive the importance of magnetic fields in interstellar gas clouds, and has made many contributions to cosmical electrodynamics. He has clarified the nature of conductivity in ionized gases, and advanced the knowledge of the conditions for equilibrium and stability of plasmas. More recently he has investigated the conditions for thermonuclear reactions.

Sociological Studies at the University of Sheffield: Prof. R. K. Kelsall

Mr. R. K. Kelsall, at present head of the Department of Social Studies at Sheffield, has been appointed to a newly created chair of sociological studies. Mr. Kelsall was educated in the University of Glasgow and graduated M.A. with honours in political economy and history. He was awarded a Clarke postgraduate scholarship and a Leverhulme research grant, and also the Gladstone Prize. In 1933 he was appointed lecturer in the Economics and Commerce Department of University College, Hull, and was made head of this Department in 1939. In 1944 he took up an appointment as research officer in charge of the Ministry of Town and Country Planning's regional research unit for Birmingham and the West Midlands, and held this appointment until 1950, when he was appointed senior research officer in charge of the Nuffield Sociological Research Unit at the London School of Economics. He was appointed head of the School of Social Studies in the University of Sheffield in 1957, the post he now holds. Mr. Kelsall has had wide experience of many different kinds of social surveys, and has published many articles and several books on the results of his work.

Institution of the Rubber Industry: Awards

DR. ERICH KONRAD, formerly director of the Leverkusen Laboratories, Farbenfabriken Bayer, has been awarded the Colwyn Medal of the Institution of the Rubber Industry, the highest honour of the Institution, for conspicuous services to the rubber industry especially in the field of synthetic rubber development. As an assistant in the Chemical Institute of the University of Freiburg, Dr. Konrad entered the field of high-polymer chemistry. With his appointment in 1927 to Bayer at Leverkusen, his work received a decisive turn towards the chemistry and technology of rubber. His work on rubber synthesis reached the point of practical application in the setting up of synthetic rubber plants as early as 1936, and was recognized by the award of the Gold Medal by the Committee of the International Exhibition in Paris, 1937. The work of Dr. Konrad is one of the foundation stones on which the present-day synthetic rubber industry is built, and his rich experience in this field has given a decisive impetus to the development of new elastomers and new types of foamed materials.

The Hancock Medal of the Institution for 1960 has been awarded to Mr. C. B. Copeman, chairman of Maclaren and Sons, Ltd., publishers, for outstanding services to the Institution and the rubber industry.

Selby Fellowship: 1960 Award

DR. W. DEUCHARS, of the United Kingdom Atomic Energy Authority, has been awarded the Selby Fellowship for 1960. The award was established last year (see *Nature*, 184, 684; 1959) "to recognize that, whereas there are numerous scholarships that enable Australian graduates to proceed overseas for research experience, there is now a need for measures to bring young graduates from British and other overseas universities for postdoctoral work in Australian laboratories". The award, which is being administered by the Australian Academy of Science, Canberra, is normally for one year's work in an Australian university or research institute in any branch of physical or biological science. It carries a stipend of £A.1,500, and up to £A.500 of the holder's travel costs are met. Dr. W. Deuchars will go to Canberra and will work with Prof. E. W. Titterton at the Australian National University, Canberra. Applications for the next award close on August 31.

U.K. Commonwealth Scholarship Commission

FOLLOWING the setting up in the United Kingdom of the Commonwealth Scholarship Commission early this year under an Act of Parliament (see also this issue of *Nature*, p. 441), it has now been decided to award about 220 scholarships tenable in the United Kingdom from October onwards. The majority of these scholarships will be at the postgraduate-level and for two years, covering the cost of fares, tuition fees and living expenses while the holder of the scholarship is in the United Kingdom. The Commonwealth Scholarship Commission has now issued its first list of recipients for the award. This list of successful candidates covers nine Commonwealth countries and includes 66 awards, of which 44 are for scientific subjects. The distribution of these first scholarships is as follows: Canada, 18 (9 scientific); Australia, 16 (10 scientific); New Zealand, 10 (8 scientific); Ceylon, 6 (5 scientific); Hong Kong, 8 (5 scientific); Kenya, 3 (all scientific); Singapore, 3 (2 scientific); Tanganyika, 1 scientific; and Uganda, 1 scientific.

Road Research

DELEGATES from thirteen member and associated countries of the Organization for European Economic Co-operation have recommended that an international body should be set up to foster road-safety research. It is suggested that the international body should be responsible for co-ordinating the research effort of the various countries concerned; to foster the interchange of road-research information; and to recommend new researches on problems the solution of which requires, or would profit from, international co-operation. It was also recommended that each country should set up a national committee for road-safety research which would, in addition, provide a link with the proposed international body.

Integration of the Cape and Royal Greenwich Observatories

THE merging has been announced of the Cape Observatory with the Royal Greenwich Observatory under the Astronomer Royal. The Astronomer Royal and H.M. Astronomer at the Cape of Good Hope have been, and will continue to be, responsible to the Admiralty through the Hydrographer of the Navy. The Cape Observatory fulfils, in the southern hemisphere, much the same functions as those performed in the northern hemisphere by the Royal Greenwich Observatory the work of which it supplements, and there will be many advantages to be gained from the integration of the two Observatories.

Nature Conservation in Wales

THE Nature Conservancy has recently announced developments in its work in Wales, including the establishment of a new Nature Reserve at Cwm Glas, Crafnant, which, lying at the head of an upland valley, runs south-west for a distance of four miles from Trefriw in the Conway Valley. The Reserve covers 38 acres of glacially over-steepened slopes, broken by rock outcrops, and culminating in the summit of Moel Wen. It lies on basic volcanic rock and has a rich flora, including a number of arctic-alpine species, which are here growing at a relatively low altitude. There is a remnant ash-wood with a rich ground flora, and while the predominant tree is ash there are, in addition, many exceptionally large hawthorns. Together with plants typical of lowland woods and fertile soils the wood contains rock stonecrop, orpine and hart's-tongue fern, which are more particularly characteristic of such shaded, rocky places in western Britain.

Further to the establishment by the Nature Conservancy in 1955 of the Newborough Warren Ynys Llanddwyn Nature Reserve, Anglesey, and additions in 1956 and 1959, the Conservancy has now purchased another 78 acres. The Reserve now covers 1,470 acres and has a coast line of 10–11 miles. The area is of great ecological and physiographical interest, as the boundary between mobile and fixed sand and the gradation between open and closed plant communities pass right through it. Extensions are also announced to the Coed Rheidol Nature Reserve, near Devil's Bridge in Cardiganshire, and the Reserve now covers an area of 89 acres. Coed Rheidol is an interesting example of a moist, mossy sessile oak wood with a rich associated flora and fauna which have developed under conditions of high humidity and heavy rainfall.

British Poultry Science

When journals are being born at the rate of about two a day, the need for each new-comer must be scrutinized carefully. *British Poultry Science*, which has just been issued, is intended to be an international journal for the publication of original researches on the fowl, and for review articles (1, No. 1; April 1960. Pp. 72+xvi. Initially two numbers annually, published in April and October. Annual subscription, 30*s.*; U.S.A. and Canada, 5 dollars. Single issues, 17*s.* net; U.S.A. and Canada, 2.75 dollars net. Edinburgh and London: Oliver and Boyd, Ltd., 1960). The contents of the first number give no indication of how it is to differ from, or improve on, the established journals which already cover this field, and, indeed, some of its contents have already been published in part elsewhere. Its further aim of bringing within its covers all kinds of scientific work on the fowl is also open to question, if only because research workers prefer to publish by discipline rather than by organism (and libraries also choose to purchase on this basis). The fowl is perhaps unique among animals in already having journals devoted to it; but it is not clear that they have stimulated fundamental work on the biology of the fowl. It seems more likely that this stimulus will come from the rapidly increasing technical requirements of the poultry industry, which, in many aspects, have already outgrown their scientific base. If this new journal is to prosper, its policy will have to be more clearly defined, particularly with respect to its emphasis on pure and applied science, and towards its anticipated lay readership.

Local Health Service

Six pilot studies into local health carried out under the direction of governments throughout the world are discussed in the first part of a report called "Local Health Service", by the World Health Organization (Report Series, No. 194. Pp. 49. Geneva: World Health Organization; London: H.M. Stationery Office, 1960. 2 Swiss francs; 3*s.* 6*d.*; 0.60 dollars). The Expert Committee on Public Health Administration in this, its third report, reaches the conclusion that the methods used are generally sound, and that, in the development of health services locally, such studies should become a routine procedure, not only as a means of assessing what services exist but also as a preliminary to the setting up of new services. The Committee discusses some of the factors affecting local health services: the need for decentralization of health services and for an efficient local administration; the various methods of organizing community effort in public health work; the importance of a closer alliance between general medical practice and local health service, and the consequent need for inculcating a proper approach to public health in the undergraduate medical curriculum; and the problems of urbanization arising from the great influx of people into the towns in response to industrial demand.

Unesco Fellowships for Electronic Computing Research

The United Nations Educational, Scientific and Cultural Organization is offering six fellowships to be shared among member States to enable highly qualified specialists to undertake research in the use of electronic computers for the purpose of mechanical translation, the theory of switching or the use of computers for the reduction of geophysical data. The fellowships will normally be for six months and will carry a travel grant and a monthly allowance varying according to the country of study. Further information can be obtained from the United Kingdom National Commission for Unesco, Ministry of Education, Curzon Street, London, W.1.

University News:

Belfast

Among recent appointments to lectureships are the following: Dr. N. T. Dunwoody (engineering mathematics) and Mr. R. G. A. Stretch (psychology).

Birmingham

Dr. I. E. Bush has been appointed to the Bowman chair of physiology and to the directorship of the Department of Physiology from October 1. Dr. Bush has been a member of the external staff of the Medical Research Council since 1958, and is also a Senior Research Fellow at New College, Oxford.

The title of professor of physiological chemistry has been conferred on Dr. W. V. Thorpe, who is at present reader in chemical physiology, as from October 1.

The following appointments are also announced. *Lectureships:* Dr. J. D. Dowell, Dr. P. Swinbank and C. P. van Zyl (physics); Dr. J. M. Webber (chemistry); K. Foster (mechanical engineering); Dr. G. W. Rowe (industrial metallurgy); Dr. V. J. Emery (mathematical physics); Dr. E. F. Stack-Forsyth (electrical engineering); R. N. Morris (econometrics and social statistics). *Research Fellowships:* Dr. T. F. Tuan (mathematical physics); Dr. N. Pessall and B. Cockayne (physical metallurgy); D. J. White to be Kenward Memorial Fellow (engineering production); H. R. Shaylor to be Staff Fellow in nuclear physics in the Department of Physics.

Bristol

Prof. T. K. Ewer, at present professor of animal husbandry in the University of Queensland, has been appointed to the chair of animal husbandry. The following appointments are also announced. *Lectureships:* Dr. P. C. Caldwell (biochemistry within the Department of Zoology); A. J. B. Cruickshank (physical chemistry); Dr. I. O. Sutherland (organic chemistry). *Research Fellowship:* Dr. P. H. Fowler (physics).

Edinburgh

The following appointments have been announced: *Readerships*, Dr. J. P. Duguid (bacteriology) and Dr. C. A. Beevers (chemistry); *Lectureships*, J. R. Small (accounting and business methods), Dr. C. G. Thomson (clinical chemistry), Dr. D. J. McAuliffe (ophthalmology), and Dr. F. M. Martin (public health and social medicine).

Leeds

Dr. F. Hepburn has been appointed lecturer in medical physics.

Among the grants in aid of research which have recently been announced are: £5,000 to the Department of Physics from the Department of Scientific and Industrial Research; £2,100 to the

Department of Civil Engineering from the Cement and Concrete Association; 7,000 dollars to the Department of Biomolecular Structure from the Muscular Dystrophy Association of America.

London

DR. C. B. B. DOWNMAN has been appointed to the Sophia Jex-Blake chair of physiology at the Royal Free Hospital School of Medicine; Dr. I. Doniach to the chair of morbid anatomy tenable at the London Hospital Medical School; and Dr. J. Hamilton to the second chair of physics tenable at University College. Among the appointments to readerships are: Mr. A. J. Buller (physiology), tenable at King's College; Mr. J. C. de Courcy Henderson (reinforced concrete structures), tenable at the Imperial College of Science and Technology. Titles of "professor in the University of London" have been conferred on Dr. H. Elliot (physics), in respect of his post at the Imperial College of Science and Technology, and on Dr. W. J. Hickinbottom (organic chemistry), in respect of his post at Queen Mary College. Titles of professor emeritus have been conferred on Prof. T. J. Bosworth (veterinary pathology), Prof. E. S. Pearson (statistics), Prof. Dorothy S. Russell (morbid anatomy), Prof. W. Smith (bacteriology), and Prof. E. E. Turner (chemistry).

Prof. E. T. C. Spooner, University professor of bacteriology and immunology, London School of Hygiene and Tropical Medicine, has been appointed dean of the School in succession to the late Sir James Kilpatrick.

Sheffield

THE following appointments to lectureships have been announced: Mr. F. W. G. Warren (applied mathematics); Dr. D. N. Jones (chemistry); Dr. R. N. Dixon (chemistry); and Dr. J. M. West (metallurgy).

"Roughness of the Moon as a Radar Reflector"

THE portion of this issue of *Nature* including the communication with the above title (p. 490) was printed before the mistake referred to below was noticed. Dr. B. H. Briggs writes: "Owing to an unfortunate error, the dotted curve in the graph is approximately $\exp(-20\,\theta)$ and not $\exp(-10\,\theta)$ as stated. The detailed agreement between the optical observations and the radar results of Hughes is therefore not as close as was originally thought, though it remains true that both methods indicate a mean slope of the order of 3°. I am indebted to Dr. Hughes for pointing out the above error".

Announcements

THE Medical Research Council's Neuropsychiatric Research Unit, under the direction of Dr. D. Richter, has been transferred from the Whitchurch Hospital, Cardiff, to the Council's Laboratories at Carshalton, Surrey.

DR. R. L. SMITH-ROSE, who is retiring from the post of director of the Radio Research Station of the Department of Scientific and Industrial Research (*Nature*, 185, 353; 1960), has been appointed chairman of the Post Office Frequency Advisory Committee in succession to Sir Lawrence Bragg.

PROF. F. D. RICHARDSON, professor of metallurgy in the Imperial College of Science and Technology, London, will deliver the fourth Robert Horne Memorial Lecture of the Society of Chemical Industry in the Chemistry Department, University of Bristol, on September 29, at 6.30 p.m. He will speak on "The Extraction of Metals and the Chemistry of Metals". The Lecture is open to the public.

AN international colloquium is to be held at the University of Grenoble on "The Physics of Electrostatic Forces and Their Applications" during September 27–October 1. The Colloquium is organized by Le Centre National de la Recherche Scientifique. Further information can be obtained from Prof. Noël Felici, Faculté des Sciences, Université de Grenoble, Grenoble.

THE European Association for Potato Research has announced its intention to organize a series of triennial conferences to review the position of potato research. The first of these conferences is to be held at Brunswick during September 12–17. Further information can be obtained from Tagungsbüro der EAPR, Institut für Pflanzenbau und Saatguterzeugung, Bundesallee 50, Brunswick.

THE Plastics and Polymer Group of the Society of Chemical Industry has arranged a three-day symposium on "High-temperature Resistance and Thermal Degradation of Polymers", to be held during September 21–23 at the William Beveridge Hall, Senate House, University of London. Further information can be obtained from the Convenor, Plastics and Polymer Symposium Sub-Committee, 14 Belgrave Square, London, S.W.1.

THE Institution of Gas Engineers and the Corrosion Group (Birmingham and Midlands Section) of the Society of Chemical Industry are organizing a joint symposium on "The Protection of Gas Plant and Equipment from Corrosion", at the College of Advanced Technology, Birmingham, during September 22–23. Further information can be obtained from the Symposium Secretary, Department of Chemistry, College of Advanced Technology, Costa Green, Birmingham, 4.

THE Chemical Society of London has announced that it will consider a number of applications for the assistance of research in any branch of chemistry. About £700 per annum is available for this purpose. Applications should be made to the General Secretary, The Chemical Society, Burlington House, Piccadilly, London, W.1, not later than November 15.

THE Commonwealth Scientific and Industrial Research Organization (Australia) has issued a List of Publications to December 31, 1959, including both those of the Organization itself and of its predecessors (Pp. 45. Melbourne: Commonwealth Scientific and Industrial Research Organization, 1960). The publications are arranged under handbooks and monographs: journals; bulletins; pamphlets; circulars; land research series; soil publications; leaflets; semi-technical periodicals; divisional publications; and miscellaneous publications. There is also a subject index.

ERRATUM. In the communication entitled "Two Types of Catalase-like Activity in the Lactic Acid Bacteria", by R. Whittenbury, in *Nature* of July 30, p. 433, there is an error in Table 1. The number of catalase-positive organisms recorded for *L. cellobiosus* and *L. viridescens* are 2 and 0, respectively; they should read 0 and 2.

THE JOHN INNES INSTITUTE

THE fiftieth anniversary of the John Innes Horticultural Institution was celebrated on July 8. The occasion served not only to recall the past achievements of the Institution, but also to announce some major new developments. These included a change in the title of the Institution, an extension of the scope of its activities and the opening of a new laboratory building.

Cell Biology and the construction of a large building to house it represent a new departure. The Cell Biology Laboratory (Fig. 1), shown in the photograph, was erected by the Trustees of the John Innes Charity and is being supported by the Agricultural Research Council. When fully equipped and staffed, the new building will provide excellent research facilities for some twenty-five scientists.

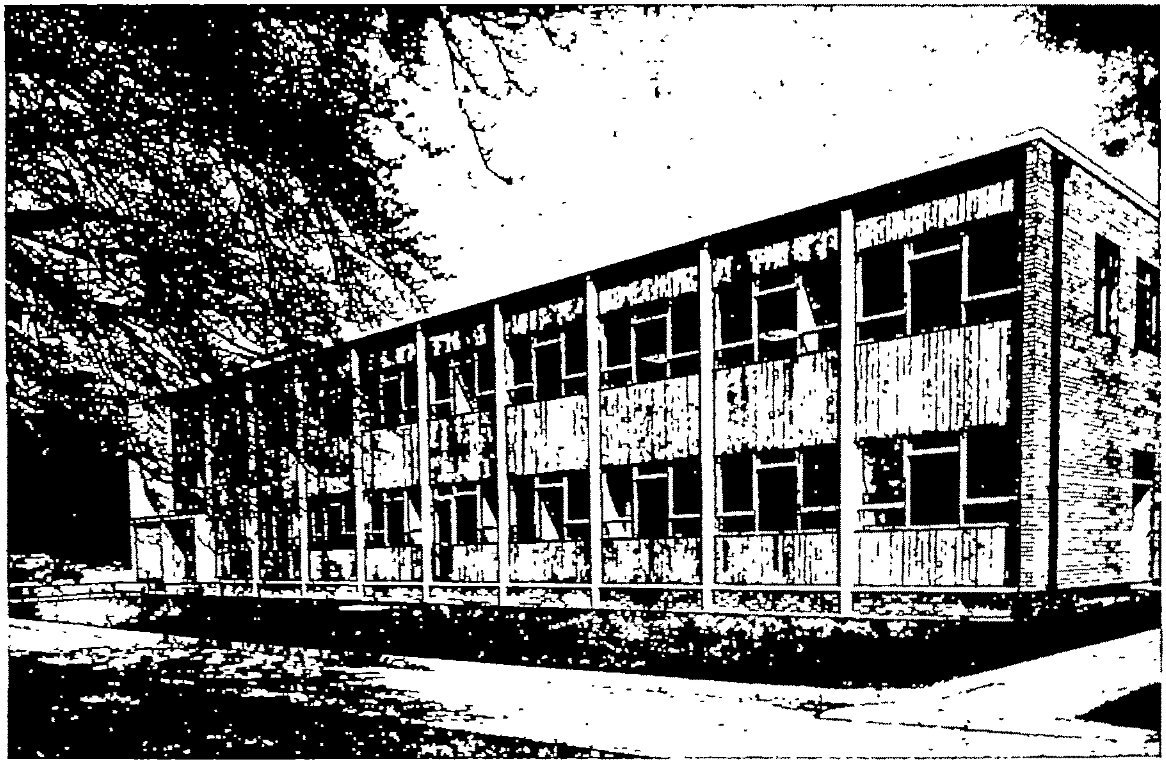

Fig. 1. The Cell Biology Laboratory, John Innes Institute

The John Innes Horticultural Institution was founded under the will of John Innes, of Merton, and began its life in that London suburb in 1910. William Bateson was the first director, and it was he who chose genetics and cytology as subjects for investigation; work which reached its climax just before the Second World War, when C. D. Darlington had published "Recent Advances in Cytology" (1932) and "The Evolution of Genetic Systems" (1939). Some of the other books published by members of the staff during this pre-war period were: "Recent Advances in Plant Genetics" (1932) by F. W. Sansome and J. Philp, "The Genetics of Garden Plants" (1934) by M. B. Crane and W. J. C. Lawrence, and "Practical Plant Breeding" (1937) by W. J. C. Lawrence. With the resumption of full-scale research activities after the War, there came K. Mather's work on quantitative variation and his book "Biometrical Genetics" (1949).

While the tradition in genetical studies is being maintained with the recent appointment of Dr. J. R. S. Fincham to take charge of the Department of Genetics, the establishment of a Department of Cell Biology and the construction of a large building to house it represent a new departure.

The Department of Cell Biology has no categorical commitment, and its members will be free to pursue their own research interests within the very wide framework implied by the term 'cell biology'. One of the features of the Department is the fact that facilities are available for work on both animal and plant material, and a new animal house is being built to meet the demands imposed by the work on animal cells. It is hoped that this fusion of disciplines and the wide variety of techniques which it involves will provide unique opportunities for the intimate exchange of ideas and experimental skills. The new Department thus represents the fulfilment of hopes originally expressed by Bateson himself, who made it a condition of his appointment as the first director that he should be allowed to carry out studies on animals as well as plants. Dr. Henry Harris, of the Sir William Dunn School of Pathology, Oxford, has been appointed head of the new laboratory.

The original name of the Institution was felt to be too restrictive to embrace the activities which are being undertaken, and the title has now been changed to the 'John Innes Institute'.

K. S. DODDS

THE WORLD HEALTH ORGANIZATION

THE annual report of the Director-General of the World Health Organization for 1959 shows the wide range of the assistance given by the Organization to countries throughout the world, both directly in the form of projects adapted to particular needs, and through international technical services of the more traditional type[*].

The 'project list', occupying more than half the volume, gives particulars of the projects, numbering more than 500, in which the World Health Organization has been co-operating with the Governments of some 140 countries, sometimes in conjunction with other organizations. A summary narrative for each project states its aim, the nature of the assistance and progress made during the year, and adds, where possible, an assessment of the results obtained. The list, grouped by country and subject title under each of the six regions of the World Health Organization, includes inter-country and inter-regional projects in which help is given to groups of countries working together on common problems—a type of project that appears to be increasing in importance.

In his introduction, Dr. M. G. Candau, director-general of the Organization, directs attention to the fact that in 1959 the Organization's work was carried on "against a general background of reduced tension in international affairs" and of "substantial improvement of economic conditions throughout the world, particularly in Europe"; and he finds growing evidence of the determination of world leaders to devote more of their countries' resources to help nations still in the early steps of technological and economic development to raise their standards of living.

In discussing some of the changes of emphasis in the Organization's programme, the director-general points out that communicable diseases remain one of the world's most serious health problems. For some, more knowledge is required; for others, such as malaria and smallpox, the methods are broadly known and what is wanted now is organization, trained staff and money.

Among diseases calling for increased vigilance are the treponematoses. More than 100 million people still live in low-prevalence yaws areas, in several countries there has been a disturbing recrudescence of venereal syphilis, and a growing incidence of gonorrhoea has been found in 15 out of 22 countries surveyed. Investigations are being pursued in order to ensure that the most effective assistance can be given to countries combating these problems.

With tuberculosis, recent findings which show that domiciliary chemotherapy may for most cases be as efficacious as treatment in sanatoria are of particular importance to the many countries where there is an acute shortage of sanatoria beds.

Mention is also made of the newer developments against leprosy, bilharziasis, poliomyelitis and the zoonoses, and of preparatory work with the view of eradicating smallpox.

Much preparatory work has been done during the year for the expansion and intensification of the medical research programme. Main targets and priorities, established with the guidance of the Advisory Committee on Medical Research, include the communicable diseases (with emphasis on viruses and diseases prevalent in tropical countries); for the highly industrialized countries, the chronic diseases, particularly cancer and cardiovascular troubles; nutrition, and problems of the increased risk of exposure to ionizing radiations. The 'service to research' will include standardization of nomenclature techniques and equipment, and the expansion of, the Organization's system of international reference centres.

Emphasis is also being given to the vast programme for the improvement of water supplies for communities, which is a primary objective in the attack on the enormous problems of environmental sanitation. The programme will be carried out in collaboration with departments of public works and with public administrations and financial authorities.

Annexes to the report give details of the membership of the Organization, its Executive Board and expert committees; the main heads of the budget for 1959; and particulars of the secretariat structure and composition.

[*] Official Records of the World Health Organization, No. 98: The Work of WHO, 1959—Annual Report of the Director-General to the World Health Assembly and to the United Nations. Pp. x+283. (Geneva: World Health Organization; London: H.M. Stationery Office, 1960.) 6 Swiss francs; 10s.; 2 dollars.

THE METROPOLITAN WATER BOARD

LONDON is by far the largest town in Britain taking its raw water supplies from wells in or from rivers flowing through, a densely populated and industrialized area, and the reports of the Director of Water Examination of the Metropolitan Water Board[*] are an invaluable guide to the measures which have to be taken, and the research which has to be carried out, to obtain a safe potable water from these sources.

The first necessity is, of course, to control and restrict pollution of the raw water. A good example of what can be done is afforded by the River Lee; in spite of the growth of both population and industry in the catchment area between 1948 and 1958, the quality of the river water improved substantially during that period. This was due in part to the improvement and extension of the sewage works at Luton (including the provision of a final stage of treatment by rapid sand filtration or by micro-straining), and in part to the treatment of the sewage of several towns, including the new towns of Harlow and Stevenage, at a single works, discharging to the Lee below the Board's New Gauge intake.

Within the catchment area of the Thames there are three major establishments, at Harwell, Aldermaston and Amersham, from which radioactive effluents are discharged. These liquors, in which the level of activity permitted is very low, are regularly monitored before being released—the Harwell effluent by the Atomic Energy Authority, the Ministry of Housing and Local Government, and the Metropolitan Water Board. There is no evidence, from the Board's observations, that there has ever been any activity present, at its raw water intakes, which could be attributed to discharges from the three establishments. The concentration of activity in treated water is about half that present (from fall-out) at the intakes, both in the Thames and Lee, the reduction being due to removal of suspended matter, radioactive decay during storage, and sometimes to dilution with relatively inactive well water. A large-scale experiment was made by adding 500 mc. of strontium-90 to 1·5 million gallons of water, standing in a disused filter bed; during a period of nine months the level of activity was reduced by about two-thirds (the water contained abundant algae and much rooted vegetation), but the results suggested that grossly contaminated waters would not be rendered potable in any reasonable time by storage alone.

---

[*] Metropolitan Water Board. Thirty-Eighth Report on the Results of the Bacteriological, Chemical and Biological Examination of the London Waters for the years 1957–1958. By E. Windle Taylor. Pp. 114+4 plates. (London: Metropolitan Water Board, 1960.) 21s.

An examination of waters from a number of wells for the presence of alkylbenzene sulphonates—the anionic surface-active agents which are the basis of powdered synthetic detergents—showed that in some they were absent, but that in others they were present in concentrations similar to those found in the Thames to which sewage effluents are discharged. It is of great interest that in a well water the presence of the surface-active material may be the only surviving evidence that the water has been polluted by sewage or sewage effluent—ammonia, coliform bacteria, and the other usually diagnostic constituents of effluents having been removed during percolation of the water through the ground. These observations were made before the use on a large scale of biologically 'softer' alkylbenzene sulphonates in detergents sold in the south of England.

Continuing its work on the relation between chemical structure and susceptibility to degradation by bacteria, a wide range of organic substances has now been examined in the Board's laboratories; from this the important conclusion is reached that because of the relative immunity of chlorine-substituted organic compounds to bacterial attack, it is unwise to chlorinate effluents containing mainly organic matter; this would include sewage effluents. Chlorination of such effluents has never been widely practised in Great Britain but appears to be common in the United States, and there has been a good deal of discussion recently on the wisdom of adopting this quite expensive method of treatment.

Among the other matters dealt with in the report are the use of automatic instruments for recording concentration of dissolved oxygen (a knowledge of which is important in taking a water supply from a thermally stratified reservoir); the presence of *Salmonella* organisms in bone meal and other fertilizers; and the persistence of fluoride in water during storage in a reservoir. Considerable advances have been made in the use of the membrane filter technique in the counting of coliform bacteria; with this method the count is available after 18 hr. as against 24 hr. with the older multiple-tube technique.

EAST AFRICAN FISHERIES RESEARCH ORGANIZATION

To the scientist the annual report for 1959 of the East African Fisheries Research Organization can only be a somewhat depressing document*. When the Jinja Laboratory was established in 1947–48 together with the Lake Victoria Fisheries Service, there seemed to be some real prospect of keeping a developing fishery under full observation, and managing it in a scientific manner in the light of both the catch statistics collected by the Fisheries Service and the information on the biology of the fish acquired by the staff of the Laboratory. In the eleven years of its life the Laboratory has not only made good progress with the task assigned to it, but also made notable contributions to our knowledge of tropical waters. On the other hand, those responsible for government at the political level have signally failed to profit by the scientifically based advice tendered by the Research Organization. As a result, the fishery is rapidly declining in productivity owing to overfishing, precisely as it was predicted that it would in the absence of more stringent and effective control. That this small fishery should be following the same downward path as the internationally exploited sea fisheries, where control is so much more difficult to exercise, is a sad reflexion not only on man's cupidity but also on the lack of scientific understanding of so many of those we appoint to govern us. This last point is further emphasized by the fact that in the small staff at Jinja (a director, four research officers and two senior field officers) there is a vacancy for a fifth research officer which cannot at present be filled for lack of finance. Consequently, the work of the Laboratory is now restricted almost entirely to fish, and moreover the Lake Victoria Fisheries Service has been disbanded, though its duties have been, at least nominally, transferred to the Fisheries Departments of the three Territories concerned (Kenya, Tanganyika and Uganda). It is much to be hoped that means will be found to continue the fundamental observations on the hydrography and chemistry, and the algal and invertebrate populations of the Lake, on which the Laboratory has made such an excellent start.

A series of appendixes give in a convenient, concise and readable form the results of some of the work done at the Laboratory during the year. One of these contains important observations on the analysis of data based on gill-net catches, made by a member of the staff of the Fisheries Laboratory at Lowestoft. Another shows how easily and rapidly the very local populations of *Tilapia esculenta* in Lake Victoria can be over-fished down to a level at which the yield ceases to be profitable. A third gives briefly the results of an investigation, made by an entomologist, of the food of several of the species of fish other than Cichlidae which inhabit Lake Victoria. In contrast to the mainly herbivorous species of *Tilapia*, the species of *Alestes*, *Synodontis afro-fischeri* and *Marcusenius grahami* eat mostly insects, whereas *Barbus altianalis* and *Synodontis victoriae* get most of their sustenance from snails. Other appendixes contain shorter notes on a variety of topics, including the growth of *Tilapia zillii* in a dam and some preliminary observations on the control by fish of snails and mosquitoes in dams.

---

* East Africa High Commission. East African Fisheries Research Organization: Annual Report 1959. Pp. ii+46. (Jinja: East African Fisheries Research Organization, 1960.)

The director, Mr. R. S. A. Beauchamp, who has recently relinquished the post he has held with distinction since he opened the Laboratory in 1948, can look back on a considerable achievement. Not only have he and his colleagues laid a firm foundation of knowledge of the hydrography, chemistry and biology of at least the parts of Lake Victoria within the reach of the Laboratory, but they have also made significant contributions, briefly described in the reports of which this is the latest, to our understanding of the factors which control the productivity of tropical waters. Moreover, the Laboratory itself now has a world-wide reputation and attracts visitors from many countries.

U.S. MATERIALS RESEARCH AND DEVELOPMENT FOR NATIONAL SECURITY

A SPECIAL Committee on Scope and Conduct of Materials Research was appointed by Dr. D. W. Bronk, president of the National Academy of Sciences, to review the materials research needs of the United States with regard to national defence and the public welfare generally; to appraise the adequacy of the present research programmes to meet those needs; to consider the resources available; and to make recommendations. A report now issued under the title "More Effective Organization and Administration of Materials Research and Development for National Security" deals with the scope of materials research from the point of view of the overall adequacy of the present effort, but leaves for continuing review by the Materials Advisory Board of the National Academy of Sciences–National Research Council the question of scope in regard to the technical content of the programme[*]. The question of scope in regard to the scientific content will be dealt with in a forthcoming report of the Academy–Research Council's Committee on Perspectives in Materials Research.

The Committee found that important national security programmes, particularly in defence, nuclear energy and space-research are impeded by the inadequacy of the properties of most of the materials now available to withstand the severe temperature, pressure, radiation, corrosion and stress conditions involved and give high performance. The Committee recommends accordingly that the Government accord high priority in national security plans and programmes to the development of new and improved materials and that the relevant programmes of the agencies and departments be strengthened. The Committee recognizes that there is no simple solution, but that every level of activity needs significant strengthening. To this end it recommends greater centralization of responsibility, more support for, and more effective co-ordination of Government-sponsored materials research and development programmes; Government incentives to encourage research and development on new and improved materials; and steps to assure adequate supplies in the United States of every chemical element or material to support full production and use of new and improved materials. It also recommends improvement in the dissemination of research information and strengthening the universities in their dual role of training scientists and engineers and pursuing research. In regard to the last, the Committee endorses a recently announced programme of Government-sponsored interdisciplinary materials laboratories at several institutions of higher learning, while as regards the dissemination of information it envisages the encouragement and acceleration of publication and removal of secrecy restrictions as well as the greater support of research designed to encourage rapid exchange of technical and scientific information, including expansion and acceleration of the Critical Tables project.

EDUCATION AND INDUSTRY

BRITISH industry has traditionally been badly served by the universities and by the majority of schools. Until quite recently, they have encouraged very few of the ablest young people to think in terms of an industrial career.

The prejudice was not all on one side. The typical industrialist of not so long ago, while he was ready enough to concede the importance of craft training, and even of technical education, conceived rather narrowly, held that industry had certainly no responsibility for any but quite specialized courses, and that no useful purpose would be served by recruiting men on a basis of intellectual quality rather than skill.

Prof. D. G. Christopherson, in a recent issue of the *Esso Magazine* (Spring, 1960), suggests that, although these attitudes are changing, it is the attitude of industry which has changed most quickly and most completely in our time. Before the War, most professors of engineering spent their time resisting pressure from industry in the direction of making courses more specifically technical, so that the graduate would be better able to do a particular job immediately on joining the firm. To-day, the influence of industry is in the opposite direction. Professors of engineering are urged to keep courses general, to resist undue specialization, at least until postgraduate-level, and to include as much material as possible of a completely non-technological character. Although employers are still interested in the professional side of what the university does, most place the greatest emphasis on intellectual quality rather than on technical expertise.

There are a number of reasons for this. In the first place, as the rate of scientific and technological progress quickened, the need for people to be adaptable, quick to learn, and capable of covering a wide field has increased. It is no good giving a man a complete specialized training if what he has specialized in is obsolete before he has reached the age of thirty.

Secondly, a large proportion of university graduates do not in fact do the job for which officially they were trained for more than a quite small proportion of their careers. Finally, as industrial concerns get larger and the place of industry in the national life increases in importance, the scope of the decisions to be taken by industry become even wider, reaching far beyond the boundaries of straightforward technical questions.

There is a fruitful field for active collaboration between the universities and industry. Many students already go to industry for vacation courses. It should be possible to relate what is done in industry much more closely to the academic side than had been done in the past. It might be possible for undergraduates and even more for postgraduates to do part of their 'course work' as an investigation of some industrial problem 'in the field'. The 'sandwich courses' in the colleges of advanced technology may prove to be the pioneers in this field.

But, no matter how good an understanding is achieved between education and industry, and no matter how courses are adjusted to meet contemporary needs, education cannot be thought of as a process which finishes in the early twenties. Some sabbatical period is as essential for men in industry as in the universities. Specialized postgraduate courses on technical subjects for people released from industry are becoming commoner and better supported. The universities and particularly the faculties of science and technology must be prepared to organize more of these courses.

Advanced technical work is not the most important purpose for which industry requires its own 'sabbatical years'. There is a stage at which intellectual renewal is particularly valuable, the stage when a man emerges from a relatively specialized department and begins to take managerial responsibility over a wider field; by that time, he has enough experience to be able to appreciate what the problems of management actually are, but usually scarcely any systematic knowledge of how they have been mastered.

Education in management in Great Britain lags a long way behind that in the United States; this is a matter to which the universities must give much more serious attention. By far the greatest difficulty is the recruiting of suitable staff. Management is essentially a practical subject, and the man who is good at it wants to practise and not to instruct.

A managerial or business school recruiting 'students' from a wide variety of industries would be better than one run by one undertaking, no matter how large; this end can perhaps be most directly achieved by co-operation between the great companies in founding their own institutions rather than by working through the existing university structure.

TRAINING IN RADIOLOGICAL HEALTH AND SAFETY

On the night of October 10, 1957, the core of No. 1 reactor at the Atomic Energy Authority works at Windscale became seriously over-heated and as a consequence a fairly large amount of radioactive material escaped through the reactor stack and was deposited thinly over many square miles of north-west England. Once the alarm was given, the Health and Safety Services of the Authority went into action on their first major emergency test. Fortunately no significant harm was done to the populations of the surrounding areas, although the affair naturally received widespread publicity.

By now the 'Windscale incident' has almost passed into history, but it is interesting to find unexpected repercussions almost three years later. Following the accident, the Prime Minister set up a Committee under Sir Alexander Fleck to report, among other things, on the organization for control of health and safety in the United Kingdom Atomic Energy Authority. The report of this Committee directed attention to the serious shortage of trained radiological health and safety specialists and called for comprehensive schemes of instruction in this field as a "matter of urgent national importance". The Fleck Committee firmly placed the onus of leading the build-up of a national supply of specialists on the Atomic Energy Authority. In view of this, the Authority set up a further Committee under Sir Douglas Veale to consider what steps should be taken to provide a staff concerned with health and safety for the Authority, and for the nation as a whole, including the establishment of a national training centre*.

Although now a matter of extensive public concern, radiological health and safety are by no means a new problem. The hazards to man of ionizing radiations have been known since the early years of the century, and the distressing experiences of the early radiological workers have kept the matter well to the fore in the minds of their successors. In 1921 the first concerted effort to deal with the problem came with the publication of the first Recommendations of the British Committee for Radiological Protection. This was quickly followed by other national recommendations and by the Recommendations of the International Commission; the latter, revised from time to time, still form the basis of world-wide radiological protection measures. Until 1945, radiological safety was a matter of concern limited almost entirely to medical radiologists and a handful of physicists attached to hospitals and medical schools. The development of nuclear reactors and weapons changed the whole picture. Production and uses of ionizing radiations have increased enormously, the number of persons occupationally exposed has increased correspondingly, and we are now faced with the position that, to a greater or less degree, whole populations are at some hazard. The number of hospital physicists has increased and the atomic energy industry has recruited considerable staffs for health and safety work, but it is clear that further recruitment and the provision of specialized training are necessary if the inevitable hazards of ionizing radiations are to be kept to a minimum.

---

* Report of the Committee on Training in Health and Safety to the Authority Committee on Health and Safety, United Kingdom Atomic Energy Authority, February 1960. Pp vi+96. (London: H.M. Stationery Office, 1960.) 5s. 6d. net.

The Veale Committee estimates that in the present decade, Britain's needs will be met by recruiting and training some 500 staff at graduate level and 600 at technical level. These are modest enough figures, but they nevertheless represent a further demand on the country's already strained resources of scientific man-power. Of the graduate group, 200 are placed in Category *A*, with a requirement of good degrees in science, medicine or engineering and capacity to assume higher managerial responsibilities and play a leading part in scientific development. The recruitment of this category is likely to prove the most difficult. Establishment of a national training centre is rightly rejected by the Veale Committee and it is proposed the postgraduate training should be limited to a small number of university centres, using the normal advanced course and research studentships of the Department of Scientific and Industrial Research to support the trainees. This is probably a wise recommendation. Nevertheless, as a balanced radiological health and safety force requires primary qualifications in physics, chemistry, engineering, biology or medicine, considerable pressure will be required to overcome the blandishments of lucrative industry and professions and the temptations to do postgraduate research in the appropriate department of the young graduate's *alma mater*. A high level of altruism may be necessary if a well-qualified medical graduate is to accept the rigours of a Department of Scientific and Industrial Research studentship in an almost alien subject, in order to qualify in radiological health and safety.

The recruitment problem in the rather lower graduate category and in the technical grade, though not easy, should not prove insuperable. The Committee goes well beyond the question of recruitment and training of full-time health and safety staff. Recommendations are made on background training for groups of administrators, managers and professional workers whose duties may bring them into contact with radiations and radiation workers. Many other groups, varying from medical officers of health and general practitioners to public health inspectors, police and fire services and nurses, are likely to be increasingly involved in radiation problems, and wide dissemination of knowledge of radiation hazards and protection at a fairly elementary level becomes essential.

In some of the appendixes to the report, outlines are given of existing or proposed training curricula at levels ranging from a Ph.D. course to simple background courses. It is clear that if recruitment is satisfactory, adequate training can be made available. Eyebrows may, however, be raised in some university boards of studies at the proposal that some Ph.D. courses should be converted from the traditional British research pattern to the American form, including a high proportion of formal teaching and examinations.

Ionizing radiations have become a major and ubiquitous factor in modern life, and, as with other developments, they bring their own hazards. The vigorous implementation of the report could go a long way towards establishing public confidence that the hazards, which to many are strange and unseen, are kept within the limits which might reasonably be accepted in a rapidly developing civilized community.

J. E. ROBERTS

LOCALIZATION BY AUTORADIOGRAPHY AT −195° C. OF RADIOACTIVE AREAS IN RATS EXPOSED TO A HIGH FLUX OF THERMAL NEUTRONS: IMPORTANCE OF PHOSPHORUS-32 IN CONSECUTIVE INTERNAL IRRADIATION

By JEAN CHANTEUR and PIERRE PELLERIN

Institut National d'Hygiène, Service Central de Protection contre les Rayonnements, B.P. 30, Chatillon-sous-Bagneux, Seine

THE purpose of this present work was to localize the organs or areas of the body of a mammal capable of becoming the seat of a radioactivity induced by exposure to a flux of thermal neutrons. Autoradiography at the temperature of liquid nitrogen[1] seemed to us to be the simplest and speediest method of carrying out this localization by applying it to a young rat.

A preliminary calculation has enabled us to fix in 5 min. the duration during which such rats should be subjected to a flux of thermal neutrons (6×10^{12} n./cm.^{2}/sec.) which we had available in a large nuclear reactor so that we could both make an autoradiographic exposure in an acceptable time, and not reach an activity of the block that might be dangerous for the operators. (We thank the Service of Biology and the Exploitation Service *EL3* at Saclay which placed suitable irradiation means at our disposal for bringing this experiment to a successful conclusion.)

Rats weighing 25 gm. were placed alive, in pairs, in plastic irradiation cartridges, and the latter were conveyed by pneumatic tube to the irradiation holes of the reactor.

After 5-min. irradiation, the cartridges were removed from the reactor. We ascertained that the rats had been killed by the flux of neutrons, and that in the exposure conditions just described the dose-rate at 10 cm. from the cartridge containing the two rats was about 1 roentgen/hr. at the exit from the pneumatic tube.

With the usual precautions required by this dose-rate (screens, lead containers, remote control, etc.) we immediately proceeded to freeze the rats in liquid nitrogen (−195° C.), including them in the frozen mixture of water and alcohol, then counter-sinking the autoradiography plan according to the technique previously described by one of us[1].

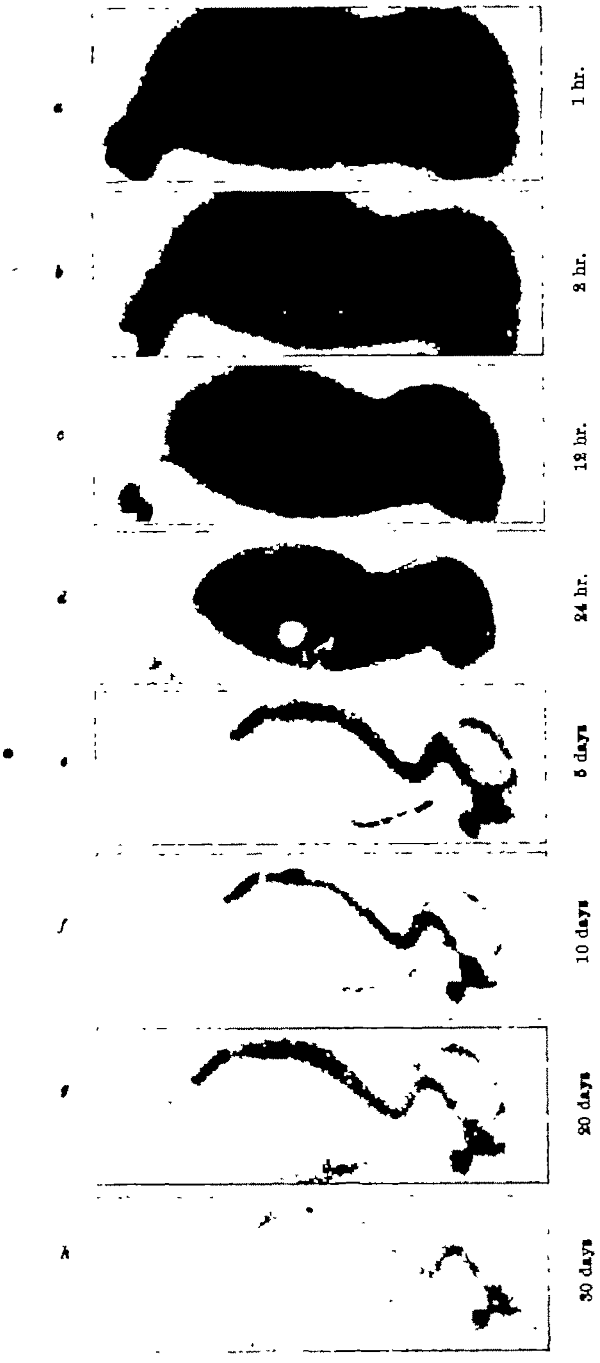

Fig 1

In order to be able to watch the relative decreases of radioactivities induced in the various anatomical areas, we have, by a series of preliminary tests, fixed the duration of the reference autoradiograph exposure at 8 min. This reference autoradiograph was then systematically carried out after increasing times from withdrawing the rats from the reactor (successively, 1, 2, 12 and 24 hr., 5, 10, 20 and 30 days after being exposed to the flux of neutrons). We have ascertained, by interposing opaque filters, that there was no low-temperature luminescence effect[3].

Fig. 1 shows the series of reference autoradiographs, on which will be noticed that immediately after withdrawal the radioactivity induced is intense over the whole of the section surface, then progressively decreases in the course of time, at the same time that considerable localizations exist in the region of the bones and teeth.

As it was probable that saturation phenomena of the photographic emulsion could explain the general blackening of the first moments, we have, for each duration following withdrawal, systematically made other exposures, shorter, on one hand, in order to distinguish possible localizations hidden by the saturation, and on the other, longer ones to emphasize localizations tending to disappear in the course of time.

We were thus able to ascertain important bony and dental radioactive localizations from the very first moments following irradiation (Fig. 2), with an autoradiographic exposure time of 1 min. which only, however, left a general fog. After six days, this fog is much reduced on the corresponding autoradiographs (Fig. 3), which nevertheless were taken with an autoradiographic exposure time of 45 min.

As could be expected, the interpretation of activation autoradiographs thus appears to be complex, and we have been led to calculate, for the chief elements forming the system, the activities induced by exposure to the thermal neutrons previously defined, by applying the formula :

$$A = \frac{0\cdot6.\Phi.\sigma}{3\cdot7 \times 10^{10} M} \left\{1 - \exp(-0\cdot69)\frac{t}{T}\right\}$$

in which Φ is the flux of neutrons per cm.^{2} and per sec., σ the cross-section in barns, M the atomic weight of the irradiated element, t the duration of irradiation, T the half-life of the isotope formed, and A the specific activity in curies per gm. The total activity of each element was then deduced from the tables, giving the detailed chemical composition of the system.

Fig. 4 shows the decrease of some of these elements in relation to time. Autoradiographic detection can only be applied to elements possessing at the same

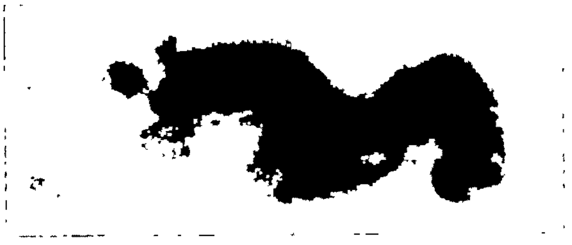

Fig 2

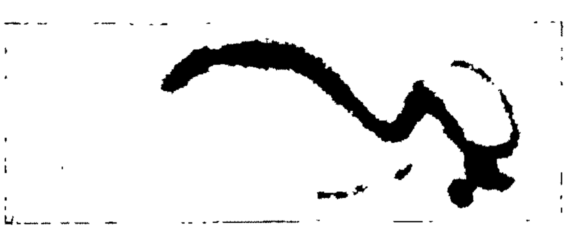

Fig. 3

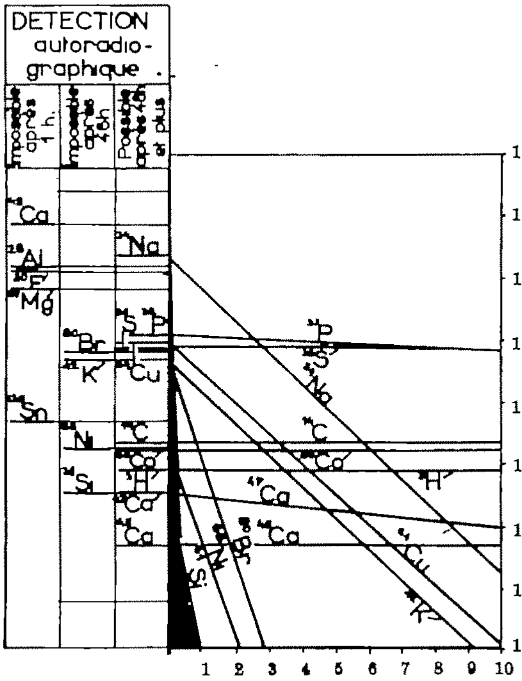

Fig. 4

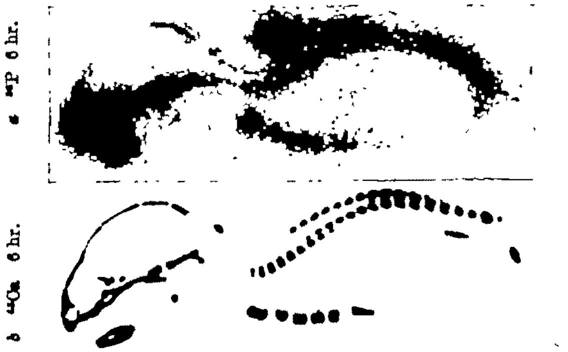

Fig. 5

time a high initial activity, a somewhat lengthy period and sufficient energy to allow of acceptable exposure conditions. The diagram shows that after some minutes, the sodium-24, sulphur-35, phosphorus-32, calcium-47 and -45, copper-64 and potassium-42 are practically alone in combining the three conditions, which confirms the comparison with the results of previous work with certain of these elements injected alone[2-4].

We may thus partly attribute the initial general fog to the even distribution of sodium-24, but its short period must appreciably reduce its autoradiographic efficiency in a few days. Sulphur-35 coming from chlorine-35, of even distribution, must also participate in the general fog.

On the other hand, it is permissible to anticipate bony localizations by activation of calcium and phosphorus in which the skeleton is particularly rich (tricalcium phosphates and apatites). Throughout the first minutes, fluorine-20 (teeth) and calcium-49 probably play an important part. Then phosphorus-32 and calcium-45 and -47 must take up the relay with slighter activity, but with a longer half-life. It should finally be possible to notice a thyroidal localization of iodine-128 during the first hour.

A systematic examination of the autoradiographs confirms these expectations on the whole: by comparing the various reference autoradiographs during a space of time (8-min. exposure), we notice that the intense fog of the first hours (Fig. 1*a*) has practically disappeared in five days (Fig. 1*e*), which enables it to be attributed to elements evenly distributed over periods of less than 24 hr. (sodium-24 and potassium-42). The bony and dental localizations that are perceived from the first hours for exposure times of 1 min. (Fig. 2) remain detectable; on the other hand, up to four weeks for the reference exposure of 8 min. (Fig. 1*h*). The decrease in blackening corresponding to these localizations is attributable to a radioelement of a period of about two weeks, and it thus seems that it is essentially phosphorus-32 which is the cause in this case, much more so than a long-period radioactive calcium, which is, moreover, in a thousand times lesser proportion as shown by the diagram. The comparison with the autoradiographs obtained by the same technique after injecting phosphorus-32 (Fig. 5*a*) and calcium-45 (Fig. 5*b*) confirms this interpretation, for the autoradiograph of the activated rat (Fig. 2) has a striking resemblance to that of the rat that has received the injection of phosphorus-32 (Fig. 5*a*) both by its localizations as well as the absence of sharpness due

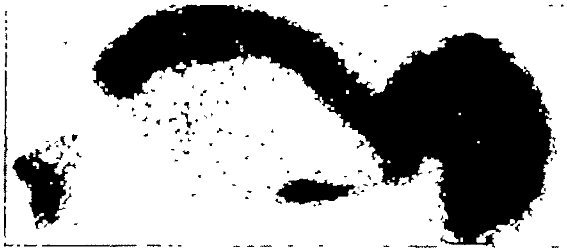

Fig. 6

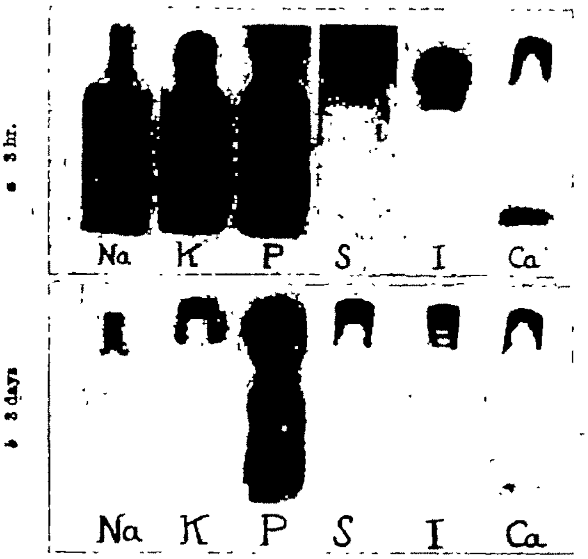

Fig. 7

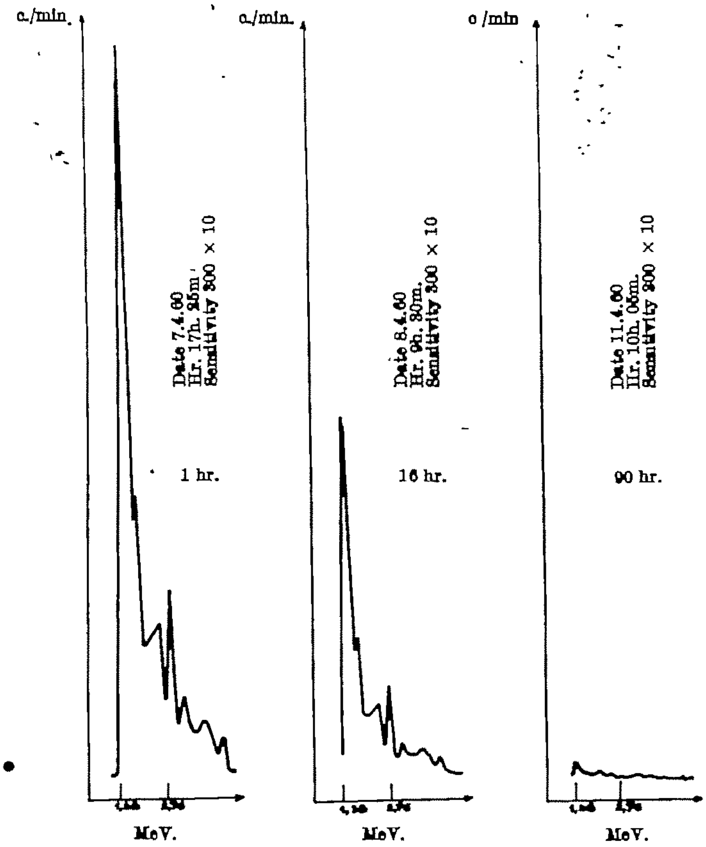

Fig. 8

to the very penetrating beta-ray emission of phosphorus-32. It should be noticed that after several days (Fig. 6) it is possible to find an appreciable background fog with an exposure distinctly greater than the reference exposure (1 hr. 30 min.); the appearance then becomes rigorously identical with that of the autoradiographs following injections of phosphorus-32, which leads one to think that this background fog is due to the activation of cellular phosphorus and more particularly nucleic acids.

As for iodine-128, which should be found in the region of the thyroid, it was not possible to show this in the conditions of these experiments, undoubtedly on account of its very short period.

In order to check these interpretations, we exposed to the neutrons flux plastic flasks of solutions titrated with soda, potash, phosphoric acid, sulphuric acid, iodine and lime, at the same concentration as in the rat's system. The flasks were autoradiographed following the same technique, and we ascertained (Fig. 7*a*) that after equal exposures on the first day, sodium-24, potassium-42 and phosphorus-32 give an intense blackening, sulphur-35, iodine-131, calcium-47 and -45 a slight or zero blackening. On the third day (Fig. 7*b*), with the same exposure time, all the blackenings are practically nil, except for phosphorus-32.

Finally, we carried out the gamma spectrometry of a rat on emerging from the pile and on the following days (Fig. 8). The appearance of the spectrum and its decrease in relation to time in identical spectrographic conditions confirm the relative importance of sodium-24 among the gamma emitters brought into play during the first days[6].

In conclusion, it appears that an exposure to a flux of thermal neutrons must secondarily involve, by the radioactivity induced in the body, a general irradiation of relatively short duration by gamma-rays of sodium-24 and potassium-42, and a much longer irradiation by the beta-rays of phosphorus-32 and, to a certain extent, of calcium-45, essentially localized in the skeleton. This latter conclusion must lead to considering the bone marrow as a critical organ with regard to irradiation by thermal neutrons. At the same time it is advisable to emphasize the preponderating part played by phosphorus-32 in this irradiation, which is both dangerous somatically by the elective irradiation of the bone marrow by beta-rays and genetically by the activation of nucleic acids.

EFFECTS OF LINEAR ENERGY TRANSFER ON THE RADIOLYSIS OF WATER AND HEAVY WATER

By Dr. E. COLLINSON, Prof. F. S. DAINTON, F.R.S., and J. KROH

Department of Physical Chemistry, University, Leeds, 2

THE primary act in the decomposition induced by X- or γ-rays of water may be represented by the equation (1), and earlier work both in these laboratories[1] and elsewhere[2] has established:

$$G_{-\mathrm{H_2O}}\mathrm{H_2O} \xrightarrow{X,\gamma} G_{\mathrm{H}}\mathrm{H} + G_{\mathrm{OH}}\mathrm{OH} + G_{\mathrm{H_2}}\mathrm{H_2} + G_{\mathrm{H_2O_2}}\mathrm{H_2O_2} \qquad (1)$$

and that when heavy water is used instead of ordinary water, $G_{\mathrm{H_2}}/G_{\mathrm{D_2}} > G_{\mathrm{D}}/G_{\mathrm{H}} > G_{\mathrm{OD}}/G_{\mathrm{OH}} > G_{-\mathrm{D_2O}}/G_{-\mathrm{H_2O}} > 1$. When radiations of very high linear energy transfer are used, the observed yields of hydrogen ($G(\mathrm{H_2})$) and hydrogen peroxide ($G(\mathrm{H_2O_2})$) are much larger, and there is evidence that a significant fraction of the hydroxyl radicals reacts with the hydrogen peroxide to form

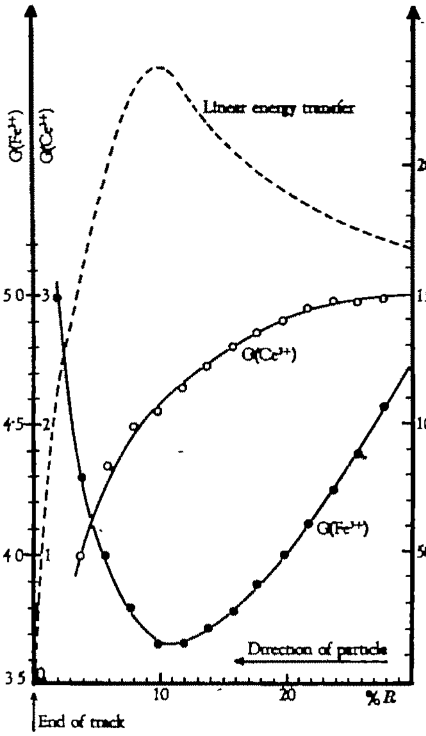

Fig. 1. $G(Fe^{3+})$ and $G(Ce^{3+})$ as a function of the percentage of the α-particle track entering the solution. Broken line is $-dE/dx$ = linear energy transfer at distances from the end of the track obtained by multiplying the abscissa by the range (40µ) of polonium α-particles in water (ref. 4)

$HO_2\cdot$ radicals and water as the track expands and before solutes can 'scavenge' them[3]. Most solutes, therefore, 'see' the primary act in, for example, the α-radiolysis of water as given by equation (2).

$$G_{-H_2O}H_2O \xrightarrow{\alpha} G_{H}H + G_{OH}OH + G_{HO_2}HO_2 + G_{H_2}H_2 + G_{H_2O_2}H_2O_2 \quad (2)$$

The aim of the work, which is briefly reported here, was to determine (*a*) whether equation (2) is valid and (*b*) the values of $G(H)$, $G(OH)$, $G(HO_2)$, $G(H_2)$ and $G(H_2O_2)$, and the effect on them of changing linear energy transfer and changing the irradiated solvent from ordinary water (H_2O) to heavy water (D_2O).

(1) *Effects of linear energy transfer.* In order to investigate the effect of the changing linear energy transfer along the α-particle track, aqueous solutions of 0·1 *N* sulphuric acid containing either (*a*) ferrous ions or (*b*) ceric ions or (*c*) ceric and thallous ions were irradiated by a flat, external α-particle source (polonium-210), the energy of the α-particles entering the solution being controlled by the use of interposed layers of mica and/or variation in the distance between the sources and the surface of the irradiated solution. An ionization chamber, similar to that described by Miller and Wilkinson[4], was employed for physical dosimetry.

Perhaps the most striking results are those shown in Fig. 1, where $G(Fe^{3+})$ for aerated ferrous sulphate solutions and $G(Ce^{3+})$ for ceric sulphate solutions are plotted against the length of an α-particle track in the solution expressed as a percentage of the length of a 5·3-MeV. α-particle track in the same solution (R).

For comparison we have also plotted the linear energy transfer in keV./µ at various distances from the end of the track, and it is most striking that $G(Fe^{3+})$ passes through a minimum when the initial linear energy transfer of the α-particle track in the solution is close to the maximum possible value for an α-particle in this medium.

The difference in position of the maximum and minimum is not unexpected, since the ordinate G corresponds to:

$$\int_0^{\%R} (dG_x/dx)\, dx$$

where G_x is the value of G for that particular linear energy transfer $(-dE/dx)$ at the point on the α-particle track a distance x from the end of the track. The minimum value of $G(Fe^{3+}) = 3·65$ is in very good agreement with the value expected from the empirical formulæ of Schuler and Allen[5], which is based on experiments with mono-energetic beams of He^{2+} ions.

The presence of thallous ions in solutions of ceric sulphate does not influence $G(Ce^{3+})$ for α-particles of energy $\lessdot$ 3 MeV., and hence *no* hydroxyl radicals are available to this solute, presumably because they are removed by reaction with one another or with molecular products. Since $G(Ce^{3+})$ increases with x (see Fig. 1) we conclude that intra-track reactions removing reducing species are occurring to a decreasing extent and that the back-reaction concerned may well be (3):

$$H + H_2O_2 \rightarrow H_2O + OH \quad (3)$$

When tritium β-particle radiation was used, both the deaerated ferrous system and the ferrous-cupric system were also studied. The value of $G(Ce^{3+})$ was found to be 2·84, which is much lower than Hardwick's value[6] of 4·54, and this and other data lead to values of molecular and radical yields (G_H = 2·9, G_{OH} = 2·1, $G_{H_2O_2}$ = 1·0 and G_{H_2} = 0·6) for acidified water, which are much closer to those for cobalt-60 γ-rays than the values hitherto accepted[7]. Consideration of this result, the data given in Fig. 1 and the value of $G(Ce^{3+})$ for γ-rays, indicates that $G(Ce^{3+})$ has a maximum value at a linear energy transfer intermediate between the mean values for polonium-210 α- and tritium β-particles. This maximum has been predicted by Burch[8], though at lower values of the linear energy transfer.

(2) *Isotope effects.* An isotope effect, similar in magnitude and sign to that observed for γ- and X-rays, was found for tritium β- and polonium α-particles. This effect at first increases with increasing mean linear energy transfer, then passes through a maximum and decreases in the region of mean linear energy transfer corresponding to low-energy α-particles. This is illustrated by the values of the ratio G_D/G_H which are given in parenthesis after the type of radiation: 220-kVp. X-rays (1·11), tritium β-particles (1·14), 3-MeV. α-particles (1·17) and 1·6-MeV. α-particles (1·04).

Associated with this effect are differences in the initial rates of formation of deuterium and hydrogen peroxides, and the steady-state concentrations of these two compounds in aerated heavy and ordinary water irradiated with tritium β-particles. Although deuterium peroxide is initially formed at about the same rate, the steady-state concentration ultimately reached is higher, and measurements of the decomposition induced by irradiation of ~ 10^{-3} *M* deuterium peroxide solution in heavy water, and hydrogen peroxide solution in ordinary water, showed that this effect is due to a more rapid decomposition of the latter.

Full experimental details and further discussion of these experiments will be published elsewhere.

We are indebted to the Polish Government and the Rockefeller Foundation for financial aid which made this work possible.

ORIENTING EFFECTS IN OCTAHEDRAL AQUATION

By SIR CHRISTOPHER INGOLD, F.R.S., PROF. R. S. NYHOLM, F.R.S., and DR. M. L. TOBE

Department of Chemistry, University College, London

IN three recent reviews of octahedral substitution[1], the subjects considered include aquation, which subsequent work[2] seems now to have appreciably clarified. This article is written because it appears possible to discuss the mechanism of aquation with more assurance than before, to interpret more fully an extended pattern of rate data, and to offer the first stereokinetic rule applicable to octahedral substitutions.

(1) Experimental Data

The experimental data are of two kinds, namely, rates of aquation, and the proportions of isomeric products formed by aquation. As to the latter, it has not always been appreciated that the products formed may be different from the products found, because the initial products undergo isomeric changes at rates often comparable to those of their formation.

In attempting to interpret these phenomena, our starting point is still the observation[3] concerning cobalt (III) aquations of the form:

$$[\mathrm{Co\ en_2}\,A\,X]^+ + \mathrm{H_2O} \rightarrow [\mathrm{Co\ en_2}\,A\,\mathrm{OH_2}]^{++} + X^-$$

that, with a constant replaced ligand *X*, a constant stereochemical relation, *cis* or *trans*, between *X* and the 'orienting' ligand *A*, and a succession of ligands *A*, taken in a presumable order of decreasing electron supply to, or increasing electron withdrawal from, the metal, the rate of aquation at first falls sharply and then rises sharply along the series. This can be illustrated more fully than before, as it is in the third column of Table 1 (en = ethylenediamine).

(2) Duality of Mechanism

Following the lines of an early theoretical treatment of similar patterns of kinetic phenomena in organic chemistry, rates such as those shown in Table 1 have been schematically plotted[3,1a,b,c] on two curves which intersect at a rate minimum; and the falling and rising curves have been interpreted as indicating different mechanisms, having different, indeed qualitatively opposite, polar requirements. Along the falling curve, an excess of electron export from the reaction site, over any electron import there may be to it, must be required in order to bring the system to the transition state: obviously, ligand loss is in the lead, as is consistent with the presumed mechanism, S_N1. Along the rising curve, an excess of electron import to the reaction site is needed in order to produce the transition state: here the binding of water must be in the lead, and the mechanism bimolecular, as is the assigned mechanism, S_N2.

In order to develop this general approach in more detail, not only with respect to the rate pattern but also in regard to the stereochemical orientation of aquation, for which the data are in the fifth column of Table 1, it is necessary to consider the electronic constitutions of the orienting ligands, and so to deduce the types of polar properties they should possess, and the effects of such properties on rate and orientation in the two mechanisms of aquation. We shall have to consider three different types of polar properties.

Table 1. RATES OF (k_1 IN SEC.$^{-1}$ AT 25°), AND ISOMER RATIOS (PER CENT CONFIGURATIONAL CHANGE) OF FIRST-FORMED PRODUCTS IN THE AQUEOUS REACTIONS

$$[\mathrm{Co\ en_2}\,A\,X]^+ + \mathrm{H_2O} \rightarrow [\mathrm{Co\ en_2}\,A\,\mathrm{OH_2}]^{++} + X^-$$

X	*A*	$10^7 k_1$	Note.	Ref.	Per cent *trans*	Note.	Ref.	Mech.
cis-Cl	OH	130,000		9	0 ?	*a*	6	S_N1
,,	N_3	2,400		12	0		12	
,,	Cl	1,250	*b*	9	0	*c*	6	
,,	NCS	114		11	0	*d*	11	
,,	NH_3^+	~5	*e*	8	0		14	S_N2
,,	OH_2^+	~150	*f*	4, 9	—		—	
,,	NO_2	1,120		3	0		3	
cis-Br	NCS	240		11	0		11	S_N1
,,	NH_3^+	15		8	0		14	S_N2
cis-NO_2	NH_3^+	180		8	0		14	S_N2
					Per cent *cis*			
trans-Cl	OH	14,000		9	some		13	S_N1^h
,,	N_3	2,500		12	20		12	
,,	Cl	160	*b*	9	some		5	
,,	NCS	0 5		7	≮50	*g*	11	
,,	NH_3^+	4		10	0		10	S_N2
,,	NO_2	9,800		3	0		3	
trans-Br	NCS	1 7		7	43		7	S_N1
,,	NH_3^+	9		10	0		10	S_N2
,,	NO_2	46,000		14	0		14	
trans-NO_2	NH_3^+	63		10	0		10	S_N2

(*a*) It is shown, though without a quantitative determination, that the initial product is at least largely *cis*.

(*b*) Half the observed rate, that is, the rate of replacement of one 'marked' chlorine atom.

(*c*) With the optically active substrate, there is complete retention of optical activity, and almost certainly of optical configuration.

(*d*) With the optically active substrate, there is a large, perhaps complete, retention of optical activity and configuration.

(*e*) Observed rate at 62·6° calculated for 25° with $E = 23$ kcal./mole.

(*f*) Half the observed rate as given for 30°.

(*g*) Probably not more than 70 per cent of *cis*-product.

(*h*) Possibly not exclusively S_N1 for *trans*-N_3 (text, section 6).

(3) Inductive Effects ($\pm I$) of Ligands

Under the term 'inductive' effects, we include all electrostatically induced deformation of electron shells within the atoms, but exclude all electron-transfer, or 'conjugative', processes.

On grounds well worked over in organic chemistry, we can at once make relative assessments of inductive polarity among some of the orienting groups of concern to us. Thus we can write the following order of increasing inductive electro-negativity (electron attraction), or, what is synonymous (for in these considerations, which are wholly relative, it is convenient to retain the alternative modes of expression), diminishing electro-positivity (electron repulsion): OH, Cl, NO_2, NH_3^+, OH_2^+. The groups N_3 and NCS need further consideration. It seems plausible to assume that the fractional charge, negative in N_3 and positive in NCS, conferred on the first atoms of the groups by the second-written and (as we think) less weighty structures of the canonical pairs:

$$.N{=}\overset{+}{N}{=}\overset{-}{N},\ .\overset{-}{N}{-}\overset{+}{N}{\equiv}N,\ \text{and}\ .N{=}C{=}S,\ .\overset{+}{N}{\equiv}C{-}\overset{-}{S},$$

will be more important for induction than the more distant, formally integral charges. We can then set down the electro-positivity differences $N_3 > NCS > NO_2$ and $N_3 > Cl$, and so build up the following more extensive series, in which some theoretically unresolved dubieties still remain:

$$\text{OH, N}_3 > \text{Cl, NCS} > \text{NO}_2 > \underbrace{\text{NH}_3^+,\ \text{en}_{1/2}^+}_{\text{standard}} > \text{OH}_2^+$$

$$\longleftarrow\!\!-\!\!-\!\!-\!\!-\ +I\ -\!\!-\!\!-\!\!-\!\!\longrightarrow \qquad\qquad -I$$

Electropositivity sequence

There is no convenient natural zero of electropositivity or electronegativity within our range of relative structural effects. We therefore choose a working zero. Among the complexes to which Table 1 refers, most of the octahedral positions are occupied by $en_{1/2}^+$ groups, and in another, less fully investigated but probably similar series, most are occupied by NH_3^+ groups. Electrostatically, these ligands must be much alike, and we could quite well adopt either as our inductive zero, as indicated in the sequence written above. Most of our orienting ligands thus become classified as inductively electropositive. The exceptions are NH_3^+, which we take as inductively neutral, and OH_2^+, which on this scale is electronegative.

An inductive effect acts, not on stereospecifically selected orbitals but on the general electrostatic situation, and most strongly on the most polarizable electrons of the nearest atom. We may plausibly take these to be the unshared electrons of the quantum groups contributing to the valency shell of cobalt; in particular, the $3d_\varepsilon$ sub-shell of six unshared electrons, which surrounds the atom, filling up the spaces between the ligands. An inductively electropositive orienting ligand will press this electron sub-shell in all directions away from itself, between the other ligands, so causing it to encroach the more on all of them, and more especially on the *trans*-ligand. (This would be a so-called '*trans*-effect'.)

Such electropositive electron displacement will evidently affect substitution mechanism by promoting a loosening of the replaced ligand, and by retarding the entry of water. It follows that it will promote S_N1, and retard S_N2 aquation.

The summary of these conclusions is that the $+I$ effect of orienting ligands will, in the order of the electropositivity sequence given above, promote S_N1 and retard S_N2 aquation, and will do all this more strongly in *trans* than in *cis*-positions.

(4) Electromeric Effect ($+E$) of Ligands

Two conjugative, or electron-migratory, processes are factors in the overall polarity of our ligands. In this section we shall consider an electropositive conjugative effect[8,15], that is, one which transfers electrons from the ligand to the metal. It is permitted to ligands which have an unshared pair of electrons on the atom adjoining the metal. In the initial state of the reacting system, the metal has no empty orbital with which it could accept a share of such an electron pair. But in the transition state, provided that the incoming water does not become bound too early, the metal will have the emptying orbital of the outgoing ligand. Thus, if we disregard hyperconjugation, the conjugative effect under consideration is necessarily absent from the initial state, but possibly present in the transition state. That is why we sub-classify it as an electromeric effect ($+E$), rather than as a mesomeric effect ($+M$).

Among the orienting ligands we have examined, four, namely, OH, N_3, Cl and NCS, possess unshared electrons in a location in which they could conjugate as described. Theory is equivocal about the relative conjugative powers of these groups. We might expect that their property of electropositive conjugation would be ordered with some reflexion of the inductive electropositivity sequence, OH, $N_3 > Cl$, NCS. However, N_3 might have to be moved down, and NCS up, in the conjugative sequence, because the adjacent-charge rule restricts conjugation by N_3 except in its minor canonical structure, whereas NCS conjugates through its major structure in which the atoms are uncharged. Formally, the group OH_2^+ should bring up the rear of this series; but we regard the unshared electrons of that group, like those of SMe_2^+ in organic chemistry, as incapable of conjugation, so that OH_2^+ is not an effective member of the class.

Since electromeric conjugation $+E$ requires an emptying bond-orbital, it will enter into, and facilitate, only S_N1 aquations, which are initiated by ligand loss. It will take no part in S_N2 aquations, neither hindering nor helping them.

A stereochemical condition is involved in the $+E$-effect; for conjugating orbitals must be non-orthogonal. In the tetrahedral binding situations of organic chemistry, this condition is commonly fulfilled; but the prohibition of orthogonality is known, for example, in the cases summarized under 'Bredt's rule'. In octahedral situations, the rectangular bonding introduces frequent orthogonality restrictions, and we have one here. For the orbital of the ligand electrons which might conjugate with an emptying octahedral bond-orbital is orthogonal to the *trans* octahedral orbital and non-orthogonal only to the *cis*-orbitals. Thus, electromeric conjugation $+E$ is restricted to *cis*-related ligands (a '*cis*-effect').

This stereospecificity has a further possible consequence. For, if the group, which is normally the most easily replaced of the groups present, is *trans*-related to the orienting ligand, the latter may cause, in a normally less easily loosened *cis*-group, a degree of prior loosening, insufficient for its own replacement, but sufficient to allow it to engage in a tentative or complete edge-displacement involving loss of the labile *trans*-group. Thus, the substitution could involve some rearrangement, a *trans*-factor giving a *cis*-aquo-product. Such rearrangements are evidently confined to substrates with a replaced group X *trans*-situated with respect to a $+E$-type orienting group A. For a fixed orienting group, the greater the normal ease of loosening of the replaced group, the less extensive should be the rearrangement. Among our replaced groups, provided that they are compared in the same structural environment, the order of extent of rearrangement on aquation should be $Cl > Br > NO_2$.

In summary, we may say that the $+E$ effect of the orienting ligands, OH, N_3, Cl and NCS, will leave untouched S_N2 aquations, but will promote S_N1 aquations, chiefly of substrates having *cis*-related orienting and replaced groups; but in the isomeric *trans*-substrates it will induce a tendency to substitution with rearrangement, in the order $Cl > Br > NO_2$ of replaced groups.

(5) Conjugative Effect ($-T$) of Ligands

This electronegative form of electron-transfer involves conjugation the other way round, that is, between unshared electrons of the metal, and an orbital which can be emptied sufficiently in the orienting ligand to allow the latter to share them[3]. The unshared $3d_\varepsilon$ sub-shell of cobalt is the source of the electrons. Any ligand having a double bond transformable to a dipolar bond the positive end of which adjoins the metal will be able to share one pair of such electrons. At least one of the three $3d_\varepsilon$ orbitals of the metal is always non-orthogonal to the receiving ligand orbital, so that at least one pair of electrons is always available for sharing. Hence this form of conjugation belongs to the ground-state of the complex, that is, to the initial state of the reaction: in this aspect, we would sub-classify it as a mesomeric effect ($-M$). Depending on the polar needs of the reaction mechanism, it will make the transition state either easier or harder to reach, and so it will either facilitate or retard reaction. In the former case only, the possibility arises that an intensification of the conjugation will stabilize, and therefore occur in, the transition state, so making it still more accessible, and providing a further facilitation that we would sub-classify as an electromeric effect ($-E$). The conjugative effect ($-T$) includes both its mesomeric and electromeric aspects.

The only orienting ligands of those used in the present work, which have the electronic structures permitting electronegative conjugation, are N_3 and NO_2. Considerations familiar in organic chemistry lead us to place their conjugative electronegativities in the order, $N_3 < NO_2$.

By retracting part of the cobalt $3d_\varepsilon$ shell, these groups will facilitate the water uptake which initiates S_N2 aquations, and will resist the ligand loss with which S_N1 aquations must commence.

Because this conjugation of the orienting ligand is with the unshared-electron sub-shell, rather than with an orbital binding another ligand, it is not sharply stereospecific. But by withdrawing the $3d_\varepsilon$ sub-shell largely from the spaces between the *trans*-ligand and the four *cis*-ligands, it should exert its strongest influence in the *trans*-position (another '*trans*-effect').

In summary, the electronegative conjugative effect of orienting ligands, in the order $N_3 < NO_2$, will inhibit S_N1 and promote S_N2 aquations, acting thus more strongly at *trans*- than at *cis*-positions.

(6) Polar Effects on Rate

In trying to anticipate the results that might follow from the joint action of the three polar factors (sections 3–5), our main guide is organic chemical experience to the effect that, leaving hyperconjugation out of account, conjugation is nearly always more powerful than induction in the control of reactions. Thus, in arranging the sequence of orienting groups used in Table 1, we begin with the $+E$ and end with the $-T$ groups, otherwise using the order of decreasing electropositivity throughout. The major uncertainty which then remains is in the placing of the N_3 group, which belongs to both conjugative types, and possibly ought to have been entered twice in the series.

The fall of rate with decreasing electropositivity, and the succeeding rise with increasing electronegativity, have been noted before, and are the basis of the assignments of mechanism suggested in the last column of Table 1. We can now see further that, over the falling part of the rate series, rates for *cis*-isomers exceed those for *trans*, while over the rising part, the rates of *trans*-isomers are the greater, with the result that the rate minimum shifts one place on passing from the *cis*-series to the *trans*. This accords with our anticipation of stereospecific $+E$ *cis*-activations in S_N1 aquations, and of favoured $-T$ *trans*-activations in S_N2 aquations. The group N_3 remains observationally marginal; but it is theoretically ambiguous, and part of the rate for the *trans*-complex may, despite the assignment of mechanism entered in the last column of Table 1 (but see note *h*), be that of an S_N2 aquation.

(7) Polar Effects on Orientation

In aquation, the predominating tendency is to retention of configuration. For *cis*-substrates, such retention, including that of optical configuration where investigated, is total so far as is known. We can understand the general tendency on the ground that the aqueous solvation shell of the complex ion will contain an inner layer of water more or less embedded among the ligands in the structure, and that such a layer is likely to include at least one water molecule in such close juxtaposition to the replaced group that substitution, whether with loosening or binding in the lead, can be effected simply by a local exchange of these interactions, and thus without the necessity for any more widespread stereochemical disturbance.

The exceptions to total retention of configuration occur among the *trans*-substrates; and there, they are confined to those in which the orienting group belongs to the $+E$ class; but they do include all examples of this class. It can also be said that the configurational changes arise only in, but in all, those aquations of *trans*-substrates to which, on account of the rate trend, an S_N1 mechanism has been assigned. This is so much in line with what would be expected from the theory of *cis*-specificity in the $+E$-activation of S_N1 aquations[1] that it does not seem unreasonable to apply theoretically guided 'induction' to rather few experimental results in proposing the following statement of requirements for aquation with rearrangement: In octahedral aquations which replace X in filled-sub-shell complexes MR_4AX of a transition metal, M, configuration will be totally preserved, unless A and X are *trans*, and A but not R has unshared electrons adjoining M.

It is implied in the theoretical basis of this rule that the conditions for rearrangement which it gives are necessary but not sufficient. Other requirements can be foreseen, as that R must be labile enough to be loosened by the available *cis*-activation, and X not so labile as to be lost altogether independently of R loosening. However, such conditions are not sufficiently definable in terms of constitution to be incorporated in a rule, and hence we leave ours as a permissive rule.

FALL-OUT CÆSIUM IN SURFACE SEA WATER OFF THE CALIFORNIA COAST (1959–60) BY GAMMA-RAY MEASUREMENTS

By Dr. THEODORE R. FOLSOM, Dr. G. J. MOHANRAO and PERRIN WINCHELL

Scripps Institution of Oceanography, University of California, La Jolla, California

STRONTIUM-90 and cæsium-137 decay at very similar rates and relatively slowly, half in about thirty years, or less than 2 per cent a year. The rate at which fall-out is reaching the land surface has been followed by extensive measurement[1] of these nuclides in soil specimens and in various rain samples. On the other hand, the collection of similar data concerning fall-out entering the sea has been seriously limited by measurement difficulties, arising mainly from the excessive dilution and from the presence in sea water of relatively larger amounts of natural radioactivities and relatively enormous amounts of stable nuclides that interfere with chemical concentration and purification.

Fortunately for study of fall-out phenomena, the dispersal of these long-lived fission products after they have entered the sea is also of great interest in the study of food-chains, especially those directly influencing fisheries, and also in the oceanographic study of water movements and mixing. Yamagata has developed a successful technique for measuring cæsium-137 in sea water through its beta-ray after numerous steps of chemical purification; recently he has reported[2] his measurements of the recent distribution of cæsium-137 in waters close to the coast of Japan. Bowen and Sugihara, of Woods Hole Oceanographic Institution, have studied fall-out constituents in the sea for several years and have reported[3] recently on the horizontal and vertical distribution of strontium-90 in the Atlantic Ocean. They point out that their vertical profiles indicate downward mixing to depths of 300–700 metres at a rate much more rapid than might be predicted from existing radiocarbon measurements. They show that a significant amount of strontium-90 has penetrated even to a depth of 1,000 metres.

The oceans are very large, and many more of this sort of data must be collected before generalizations regarding either the arrival or dispersal of fall-out become convincing. Efforts at the Scripps Institution, therefore, have centred around simplifying the chemical assay required, adapting it to shipboard use, and the application of electronic aids wherever possible. Whereas strontium-90 emits only beta-rays and its assay in sea water is tedious, cæsium-137 (which falls into the sea at about the same rate) has both beta- and gamma-emission. To utilize the beta-ray as Yamagata and others have done, the trace of radiocæsium must be chemically separated from the large amount of potassium present in sea water, including the natural beta-emitter potassium-40. On the other hand, the modern scintillation spectrometer has no trouble resolving the gamma-ray of cæsium-137 (0·66 MeV.) in the presence of much larger amounts of potassium-40 (1·46 MeV.). The assay problem, therefore, reduces to one of concentrating sea water cæsium in a way convenient for gamma-ray spectrometry. Gustafson, Marinelli and Brar[4] at the Argonne National Laboratory have shown how low-level gamma-ray assays can be made from bulky specimens by use of large scintillation detectors. It was found at Scripps that the radiocæsium in a barrel of sea water, brought down together with roughly 30 per cent of the potassium by the mere addition of sodium cobaltinitrite, could be collected as a precipitate having a volume of about 250 ml. This wet material, placed near a 3-in. diameter sodium iodide scintillation crystal, gave accurate and reproducible measure of the cæsium content as could be established by adding known amounts of radiocæsium to controls. For this sort of work, a 256-channel gamma-ray spectrometer is now available at Scripps; a digital computer accessory developed at Scripps now permits storage of information on short magnetic tape loops and gives means for the rapid comparison between gamma spectra and the elimination of background effects. At present the precipitate is allowed to settle overnight, collected after decantation and then exposed to a 3-in. crystal, generally overnight. It is expected that gamma spectrographs will be made in less than 2 hr. by the use of larger crystals; and it is planned to have the initial precipitation carried out on board the research ship so that only the concentrated precipitate need be brought back from the longer expeditions.

Details of the procedure will appear elsewhere. Satisfactory reproduction of results has been demonstrated; the difference between the assays of five 200-litre replicate controls was less than 11 per cent. It now appears unnecessary to resort to the use of such large samples; nevertheless, several uncertainties in the early work were avoided by this means. For example, storage in full-sized steel oil drums for one month was found to cause a loss of about 20 per cent of the radiocaesium to the walls; and storage for one week in a rubber barrel caused a loss of about 13 per cent. Losses of this sort may be serious when small samples are stored for a long period, but, of course, are eliminated by immediate chemical precipitation.

Table 1 gives the results of twenty preliminary assays made on 200-litre sea water samples taken just beyond the surf zone (300 metres from shore) at Scripps pier. Serial 10 was deliberately taken when the water was brown with terrestrial mud from a heavy local rain; it is not significantly exceptional in caesium content.

The average caesium-137 is 97 micromicrocuries per kilo litre (97 $\mu\mu$c./kl.).

Table 2 shows the results for water carefully collected in 200-litre aliquots in the open sea many miles from shore. The average concentration is 138 $\mu\mu$c./kl.

For comparison there are two groups of measurements made by Yamagata[1] concerning Japanese waters. He deduced from industrial salt concentrates that coastal waters early in 1958 contained caesium-137 in the amounts 70–150 $\mu\mu$c./kl. Later, by direct low-level beta technique, he measured the concentration in 1959 surface sea water taken from salt works, reporting the average caesium-137 from fifteen samples as 380 $\mu\mu$c./kl.

Of course, too much should not be expected from cursory comparisons between these preliminary sets of measurements. It is believed that the oceanographic phenomenon called 'upwelling' does not occur in the region where the samples of Table 2 were taken; nevertheless, these waters may have been influenced by local vertical mixing of some sort, perhaps at a place thousands of miles to the north of the sampling position. The range of variation in concentrations which appear in these tables as well as in Yamagata's 1959 measurements (240–650 $\mu\mu$c./kl.) should be a warning to those who might hope to establish for specific oceanic areas the average vertical profile of radiocaesium (or radiostrontium or any other water tag) with only a few measurements.

Table 1. CONCENTRATION OF CAESIUM-137 IN SEA WATER FROM SCRIPPS PIER

No.	Date collected	CsCl carrier mgm./l.	Cs-137 $\mu\mu$c./kl.
1	11/30/59	0	76
2	12/ 2/59	0	123
3	12/ 3/59	0	104

Sample No. 5 was collected in a neoprene drum. The rest in steel drums.

The increase reported in caesium in Japanese waters between 1958 and 1959 corresponds to an increase in weapon-testing activity and to a world-wide increase in fall-out. However, the difference between the California and the Japanese surface concentrations might be due to several factors; certainly to be considered are the reports of consistently higher local fall-out in Japan, and also are the differences of positions of Japan and California in the general circulation of the Pacific relative to the weapons proving-grounds. Certainly, the behaviour of a water tag in surface-water must be explored first, but these waters move faster horizontally; much more information concerning transport and mixing can be obtained when samples from several depths can be examined. Plans therefore have been made to sample Pacific waters to depths where there is little motion.

Arrival of fall-out, being associated with rainfall, is at best spotty. However, during the past eighteen months there has been a moratorium in weapons tests; and over this period there have not appeared the large peak values witnessed during the previous years. Advantage, of course, should be taken of this simplifying circumstance to establish background values related to the ocean. Another factor arising from the moratorium should be mentioned as it concerns the measurement of radiocaesium in sea water. During the past year the shorter-lived fission products have become so attenuated that essentially nothing needs to be done now to eliminate their interference with caesium-137 in a gamma-ray spectral analysis. Prior to this recent, happy period, the obscuring effects of fresh fall-out constituents were combated at Scripps either by additional chemical treatment, or by fullest use of the digital computer already mentioned and developed for just this purpose.

The matter of vertical biological transport cannot be overlooked. However, one can present an argument for neglecting the biological transport of radiocaesium perhaps as strong as that offered by Bowen and Sugihara for ignoring this contribution in the case of radiostrontium. They argued that biological transport cannot be important because of the presence of large amounts of stable strontium and calcium in sea water. Cæsium, too, is notably soluble; only traces of the radionuclide enter as fall-out and these must share with large amounts (about 0·002 mgm./litre) of stable cæsium; and also there is present in sea water much larger amounts of potassium (about 380 mgm./litre). It is common experience that potassium and cæsium are found together in many reactions—organic and inorganic. Still, a considerable loss of radiocæsium to surfaces has been observed in the actual handling of sea water specimens, and too little is now known about the behaviour of stable cæsium in the actual seas. Fortunately, the chemical behaviour of cæsium is quite different from that of strontium; exploration based upon the progress of fall-out in the ocean should exploit this. At the outset, sampling of radiostrontium should go along with that for radiocæsium.

Various aspects of this work have been supported by the United States Atomic Energy Commission (Contract No. AT(11-1)-34, Project Agreement No. 56), and by the United States Office of Naval Research (Contract 233(34), Amendments No. 7,8,9). We are grateful for suggestions that have come personally from Drs. V. T. Bowen, T. T. Sugihara and N. Yamagata. We wish to thank D. C. Martin for related preliminary studies, and also Barbara Edwards, William Hartin and Richard Schwartzlose for skilful technical assistance.

VISCOSITY INCREMENTS OF NON-IONIZED MOLECULES

By ALFRED POLSON

Council for Scientific and Industrial Research and University of Cape Town Virus Research Unit, Medical School, Cape Town

A DISTINCTIVE property of colloidally dispersed substances as opposed to crystalloids is their relatively higher intrinsic viscosity or viscosity increment. The reason for this is that the medium in which the macromolecular particles are dispersed may be regarded as continuous on account of the great difference in size between the suspended particles and those of the medium. For such systems the frictional forces encountered by a particle moving through such a medium may be calculated from the well-known Stokes's equation. Low molecular substances (so-called crystalloids) do not obey Stokes's equation since the medium in which the molecules are dispersed may no longer be regarded as continuous. When these low molecular substances move through a medium composed of molecules of similar size they will encounter less friction than colloid particles, by slipping into empty spaces in the dispersion medium.

In viscosity and diffusion measurements with crystalloids, the slipping effect will show itself as a low-viscosity increment $[\eta]$ or as an abnormally high diffusion-rate.

Viscosity Increments of Low Molecular Substances

As might be expected, the departure from the ideal or macroscopic friction law of Stokes becomes more pronounced the more closely the molecular diameters of the dispersed particles approach those of the dispersion medium. In Table 1 and Fig. 1 are shown the viscosity increments of low and high molecular substances in water at 20° C. as a function of their molecular volumes expressed as log (MV).

The $[\eta]$ for the low molecular substances are greatly dependent on the molecular volumes, being almost zero for urea and rising to 0·024 for sucrose, and 0·035 for norleucine. An interesting conclusion may be drawn regarding the molecular state of water from the $[\eta]$ log (MV) curves. Let (MV) be the molecular volume of the dissolved substance and (mv) that of the dispersion medium. We may then write:

$$[\eta] = F[(MV) - (mv)]$$

where F is an unknown factor. Whatever F may be, $[\eta]$ will approach zero when (MV) approaches (mv). Knowing (MV) when $[\eta] = 0$ we may estimate (mv).

From Fig. 1 it is obvious that the $[\eta]$, log (MV) relationship for low molecular compounds is presented by a curved wedge which pinpoints on the ordinate at log $(MV) = 1·58$, indicating that the $[\eta]$ will equal zero when the substance under investigation

The molar volumes of the crystalloids were obtained from the publication by Longsworth (ref. 1) and from "Handbook of Chemistry and Physics" (1958–59), the molecular weights of the proteins from Svedberg and Pedersen (ref. 2), the viscosity increments from papers of Polson (refs. 3 and 4) and unpublished measurements.

* Brohult (ref. 5).

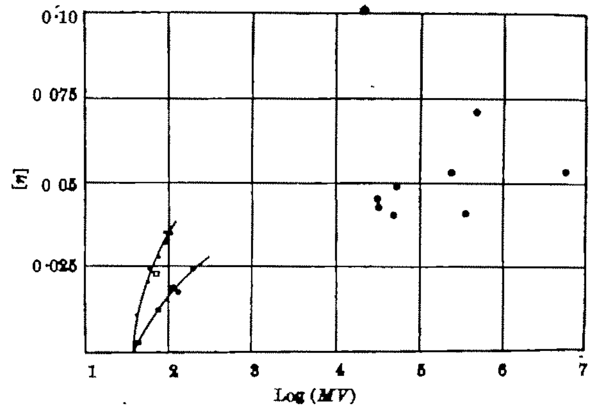

Fig. 1. Variation of [η] with log (*MV*)

The large solid circular spots are the [η]'s of the protein molecules, the small full stops those of the aliphatic amino-acids, and the open circles those of the compact molecules. The open square is the [η] of glycerol

has a molar volume of approximately 38. As the viscosity measurements were all made in distilled water at 20° C., it indicates that water has a molar volume of 38 at 20° C., therefore a molecular weight of 38 or a chemical-structure of $(H_2O)_2$. This is confirmatory evidence of the well-established fact that water molecules form aggregates of the type $(H_2O)_n$ where $n = 1, 2, 3$, etc. At low temperatures the higher polymers predominate, and at elevated thermal levels the monomers are in excess.

It is interesting to note that the top of the wedge shows the variation of $[\eta]$ with log (MV) for the aliphatic amino-acids which may be regarded as composed of rod-shaped particles, while the lower curve presents the $[\eta]$ of the molecules with more compact structures.

Viscosity Increments of Colloidal Particles

From Fig. 1 it is apparent that the $[\eta]$'s of the macromolecules are independent of molecular volume. The scattering around the mean value may be ascribed to variation in states of hydration or in particle shape.

It has been shown in a previous communication[4] that $[\eta]$, the molecular weight M, and the diffusion constant D are interrelated by the following equation:

$$[\eta] = \frac{k}{MD^3}$$

where k is an empirical constant and equal to $8{\cdot}06 \times 10^{-14}$. This equation was derived from the Stokes–Einstein diffusion equation and from Einstein's viscosity law. The empirical constant was based on a knowledge of the molecular weights of a variety of proteins as determined by the oil turbine ultracentrifuge. The value of k at 20° C. calculated from theory was $6{\cdot}16 \times 10^{-14}$. It was further pointed out that the discrepancy between the theoretical and empirical values disappears when the numerical in Einstein's equation was increased from 2·5 to 3·24. It is now generally accepted that the molecular weights of the proteins as determined with the oil turbine ultracentrifuge are approximately 10 per cent higher than the true values on account of faulty registration of the rotor temperature during operation of the oil turbine centrifuge[6]. This implies that the figure 3·24 must be reduced to approximately 2·92 for equation (1) to fit the new values of the molecular weights.

Recently Broersma[7] has re-examined the Einstein viscosity equation theoretically and found that the numerical 2·5 must be multiplied by a factor of 1·2 when applied to colloidal suspensions. The new numerical in Einstein's viscosity equation therefore becomes 3 0, which is in close agreement with the empirical value of 2·92. On introducing this new value into the equation, the viscosity increment of a protein at 20° C. should be truly presented by the equation:

$$[\eta] = \frac{7{\cdot}39 \times 10^{-14}}{MD^3}$$

This equation is free from empirical factors, and it offers a means of molecular weight determination without a knowledge of the partial specific volume of the substance under investigation, as is essential in the ultracentrifugation method.

AMINO-ACID SEQUENCE OF HUMAN INSULIN

By Dr. D. S. H. W. NICOL* and Dr. L. F. SMITH†
Department of Biochemistry, University of Cambridge

THE amino-acid sequences of insulins obtained from six species have previously been reported[1–4]. The only differences found were in the sequence of three amino-acids in the *A* chain at positions 8, 9 and 10, as shown in Table 1.

Insulin from several of these species has been used in the treatment of diabetes in man, and it was of interest to know what differences, if any, there were between these proteins and human insulin for which they were acting as a substitute.

Crystalline human insulin was prepared from pancreases obtained at post-mortem. Insulin from

individual human pancreases was purified by a method to be published at a later date. Insulin was oxidized with performic acid[5] and fractionated by electrophoresis on paper at *p*H 8·9 in a 1 per cent ammonium carbonate solution.

The amino-acid sequence of fraction *B* was determined as for previous species[2,3] by digestion with pepsin at *p*H 2 and electrophoresing the digest at *p*H 6·5, giving the peptides shown in Fig. 1. An identical pattern was obtained using cattle fraction *B* as a control. Peptides 1–8 gave identical amino-acids on hydrolysis as those obtained from cattle (Table 2). Peptide 9 was different in that it contained no alanine. On treatment of this peptide with trypsin (1 per cent in 1 per cent ammonium bicarbonate, 15 min., 37° C.) followed by electrophoresis at *p*H 6·5, two bands were obtained, one of which on hydrolysis gave the same amino-acids as the parent peptide, but moved faster; the other band was free threonine. This suggested that the C terminal peptide was Tyr.Thr.Pro.Lys.Thr. This was confirmed by treatment of fraction *B* with trypsin, when the peptide Gly.Phe.Phe.Tyr.Thr.Pro.Lys, and free threonine were obtained.

8	Phe.Val.Asp(NH$_2$).Glu(NH$_2$).His.Leu.CySO$_3$H.Gly.Ser.His.Leu.
9	Tyr.Thr.Pro.Lys.Thr.

Fraction *A* was digested with chymotrypsin (1 per cent in 1 per cent ammonium bicarbonate, 20 min., 37° C.) and after drying and electrophoresis at *p*H 3·5 gave the bands as shown in Fig. 2*a*. *AC*1 was eluted and hydrolysed with more chymotrypsin for 18 hr. *AC*2 was hydrolysed with elastase (1 per cent in 1 per cent ammonium carbonate 18 hr. 37° C.) and both electrophoresed at *p*H 3·5 (Fig. 2*b*, *c*). As shown in Table 3, *AC*1 *a*, *b*, *c* were identical with peptides previously obtained from all other species. The peptides obtained from *AC*2 together show that the sequence of amino-acids from A_1 to A_7 and A_{11} to A_{14} is the same as for all other species, and that in positions *A* 8, 9, 10 the sequence is Thr.Ser.Ileu. as had been found for pig and sperm whale insulin.

*AC*2*b*	Tyr + Leu.
*AC*2*c*	Ser.Ileu.CySO$_3$H.Ser.
*AC*2*d*	Gly.Ileu.Val.Glu.Glu(NH$_2$).CySO$_3$H.CySO$_3$H.Thr. + Gly.Ileu.Val.Glu.Glu(NH$_2$).CySO$_3$H.CySO$_3$H.Thr.Ser.
*AC*2*e*	Gly.Ileu.Val.Glu.Glu(NH$_2$).CySO$_3$H.CySO$_3$H.Thr.Ser.Ileu.CySO$_3$H.Ser.
*AC*2*f*	CySO$_3$H.CySO$_3$H.Thr.Ser.Ileu.CySO$_3$H.Ser.
*AC*2*g*	Glu(NH$_2$).CySO$_3$H.CySO$_3$H.Thr.

When some confirmatory experiments were performed using a second batch of insulin extracted from ten pancreases, large amounts of the peptide Ser.Val.CySO$_3$H.Ser. were obtained from fraction *A* in addition to the sequences previously noted. It was also possible to isolate the peptide Tyr.Thr.Pro.Lys.Ala. from a pepsin digest of fraction *B* from this batch. These sequences are identical to those obtained from cattle insulin. Total hydrolysis of a sample of fraction *A* showed the presence of both threonine and alanine approximately in the ratio 1 : 2. This suggested that both cattle and pig sequences occurred in human insulin, and it was decided to determine if some individuals had the pig sequence and others the cattle sequence.

It has been found that fraction *A* can be isolated in a pure state from crude pancreatic extracts after oxidation, by electrophoresis in 20 per cent formic acid in which fraction *A* moves to the anode, all other material remaining at the origin or moving to the cathode. Using this method, fraction *A* was prepared from several individual pancreatic extracts. In later experiments the intact insulin was isolated in pure form, and the amino-acid sequence of both fractions *A* and *B* could be determined. Depending on the amount of material obtained (the pancreases varied from 80 to 150 gm. and the maximum quantity of insulin obtained was less than 10 mgm.) either the sequence or the amino-acid composition of fraction *A* was determined. The latter is sufficient to distinguish between pig and cattle insulin as the only residue of threonine in pig fraction *A* is replaced by alanine, which also occurs only once in cattle fraction *A*.

Twelve specimens were examined in this way, and only the Thr. Ser.Ileu. sequence was found in fraction *A*. While this does not prove that only the sequence Thr.Ser.Ileu. occurs in positions *A* 8, 9, 10 in the human population, to have obtained a sample containing about 60 per cent cattle sequence as in the second batch would suggest a high frequency of occurrence and might be expected to show up at least once in a sample of twelve individuals. The five samples of fraction *B* examined had only threonine as the C terminal amino-acid. It is suggested that this second batch was contaminated with cattle insulin, and that the amino-acid sequence of human insulin is that shown in Fig. 3.

The substitution of threonine for alanine as the C terminal amino-acid of the *B* chain occurs in a part of the molecule which has been shown to be un-

essential for biological activity[6,7]. Berson and Yalow[8] demonstrated significant differences in the reaction of cattle and pig insulins with human anti-insulin serums of patients treated with mixed cattle and pig insulins. They suggested that this could be accounted for if most (or all) of the antibody produced was directed against the cattle insulin. From the close similarity of pig and human insulins, in particular the identical sequence in positions *A* 8, 9, 10, it might be expected that pig insulin would be a less-efficient producer of antibodies in man than cattle insulin.

We wish to thank Dr. F. E. Camps, Dr. D. Teare and Prof. Payling-Wright, of the University of London, for offering us facilities for obtaining the human pancreases; Dr. C. G. Pope, of the Wellcome Research Laboratories, for much assistance in extraction procedures; and Dr. F. Sanger, for encouragement and advice. One of us (D. S. H. W. N.) is indebted to the University of Cambridge for a grant from the Beebe Fund.

MECHANISM OF FORMALDEHYDE-INDUCED MUTAGENESIS. THE UNIQUENESS OF ADENYLIC ACID IN THE MEDIATION OF THE MUTAGENIC ACTIVITY OF FORMALDEHYDE

By Dr. THOMAS ALDERSON*

Institute of Animal Genetics, University of Edinburgh

IN a previous communication[1], I have reported that in experiments using a chemically defined and axenic treatment medium, formaldehyde exhibits no mutagenic activity towards *Drosophila melanogaster* by the larval feeding method, unless ribonucleic acid is present in the treatment medium. Further analysis of this phenomenon now indicates that adenylic acid is the active component of ribonucleic acid uniquely concerned; none of the remaining nucleotides (guanylate, uridylate, cytidylate) appears to be effective. Adenylate is apparently necessary in the treatment medium for the mediation of the mutagenic activity of formaldehyde.

The indication that adenylate was the most likely nucleotide to be involved came from consideration of the patterns of utilization of the ribonucleic acid nucleotides as growth requirements in *Drosophila melanogaster* larvae[2]. Essentially, purines and pyrimidines supplied singly cannot substitute completely for the ribonucleic acid polynucleotide, though adenylic acid, adenosine, guanylic acid, guanosine, and adenine all respectively increase growth in the order of effectiveness stated. Ribonucleic acid pyrimidine nucleosides and nucleotides supplied singly are not utilized; however, if either the pyrimidine nucleosides or nucleotides are administered simultaneously with adenylic acid, the growth-rate then obtained is indistinguishable from that with the equivalent amount of ribonucleic acid. When all the nucleotides except adenylate are supplied, growth is found to be even slower than in the absence of ribonucleic acid; however, when any of guanylate, uridylate, and cytidylate is supplied singly, but in conjunction with adenylate, the rate of growth is increased in each case. Thus, the requirement for ribonucleic acid is seen to be primarily a requirement for adenylate; and it might consequently be supposed that adenylate would be the most likely nucleotide concerned in the mediation of the mutagenic activity of formaldehyde. The following experiments were thus planned with these considerations in mind.

The design of experiments[1], the methods of treatment of larvae[3], and the brood-pattern determination of sex-linked recessive lethal mutation-rates[4] are as previously described. The treatment medium, as previously[1], is referred to as the synthetic medium (*sm*), when ribonucleic acid is omitted; addition of nucleotides is written as $sm + a + g + u + c$, to denote the nucleotides present. The concentration of each nucleotide is taken from the equivalent amount present in 0·4 per cent ribonucleic acid, assuming the four nucleotides are found in equimolar amounts in the ribonucleic acid polynucleotide. Thus, unless otherwise stated, each nucleotide is supplied at a concentration of 0·1 per cent, which approximates closely to the optimal concentration for the purine nucleotides on the synthetic medium[2]. Ordinary medium is the yeast–maize meal–treacle medium normally used for culturing *Drosophila* in this laboratory.

Tables 1 and 2 illustrate the results obtained when larvae are fed on *sm* + ribonucleic acid (0·4 per cent) for 15 and 18 hr. respectively, before transfer to the treatment medium for 24 hr.; after which they are allowed to complete development on ordinary food.

---

Since development is quicker when adenylate is present in the treatment medium, a treatment was carried out where development was slowed down on the adenylate-containing synthetic medium (*sm*+*a*+*g*+*u*+*c* delayed), to obtain a developmental time comparable with the treatment where adenylate is absent. This modification of the treatment medium has been used previously[1], and is achieved by halving the cholesterol concentration, and substituting 0·004 per cent choline for the lecithin. A treatment where 0·05 per cent adenine (*A*), which is approximately equimolar with 0·1 per cent adenylate, replaces adenylate is also listed; this treatment has the advantage that it gives a comparable developmental time with the *sm* + *a* + *g* + *u* + *c*, and the disadvantage that adenine is known to be anti-mutagenic for formaldehyde-induced mutagenesis on a yeast–glucose medium[3,4].

In both series (Tables 1 and 2), significant formaldehyde-induced mutagenic activity is found where adenylate is present in the treatment medium, whereas little or no activity is detectable in its absence. The first brood difference between *sm* + *a* + *g* + *u* + *c* and *sm* + *a* + *g* + *u* + *c* delayed is not significant in either series (χ^2 = 0·12 and 3·46, with 1 d.f., respectively), but whereas the second brood difference in Table 1 is not significant (χ^2 = 0·29, with 1 d.f.), the second brood difference in Table 2 is significant (χ^2 = 6·13, with 1 d.f.). However, if the two broods of Table 2 are summated, giving mutation-rates over the two broods of 1·45 per cent for *sm* + *a* + *g* + *u* + *c* and 1·27 per cent for *sm* + *a* + *g* + *u* + *c* delayed, the mutational response is approximately equal (χ^2 = 0·145, with 1 d.f.). This slight shift in brood patterns, where a decrease in the first brood response is followed by a corresponding increase in the second brood response, is usually characteristic of the presence of a slightly more advanced germ-tract during the period of treatment. This tendency is not expected after 'delayed' treatment, though it sometimes occurs (Table 2). A slight trend in this direction is also found in some 'delayed' treatments on a medium containing ribonucleic acid. Adenine, although giving a comparable developmental time with the *sm* + *a* + *g* + *u* + *c*, shows little or no effect, in keeping with its property as an anti-mutagen for formaldehyde-induced mutagenesis.

A further experiment, which was carried out together with one of the ribonucleic acid series[1], is illustrated in Table 3. Here, the mutagenic activity of formaldehyde was studied by treating 24-hr. larvae for 24 hr. on *sm*, *sm*+ribonucleic acid, and *sm*+*a*+*c*; in the latter treatment, cytidylate was added at a concentration of 0·025 per cent, since the *Drosophila* Oregon-*K* stock used has a partial requirement for cytidylate[5]. As seen, adenylate is as effective as ribonucleic acid in the level of formaldehyde-induced mutations produced.

It does not appear to matter whether adenylate is present as the free mononucleotide or bound in the ribonucleic acid polynucleotide. But the mutagenic activity of formaldehyde seems dependent on the presence of adenylate within the treatment medium, since feeding with ribonucleic acid before or after treatment has no effect. Adenylate, therefore, apparently functions within the treatment medium as the necessary mediating agent in formaldehyde-induced mutagenesis.

Reactivity of Ribonucleic Acid (and its Constituent Nucleotides) with Formaldehyde

It has been revealed by spectrophotometric methods[6] that formaldehyde actively combines with the amino-groups of the purines and pyrimidines of ribonucleic acid; the binding of formaldehyde by ribonucleic acid polynucleotides appears to be a specific function of the amino-groups of their bases[6,7]. This has been further demonstrated by the reactivity

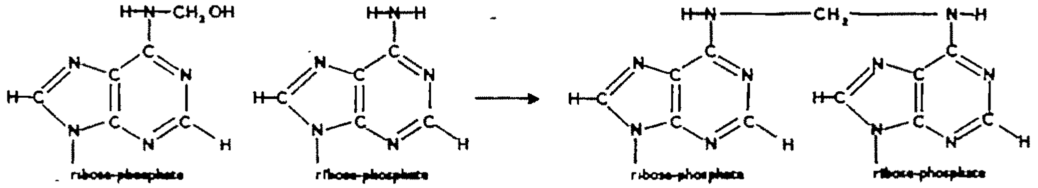

Fig. 1. Methylene bridge formation between the amino-groups of two adenylic acid molecules

of formaldehyde with various synthetic polynucleotides[7]; only polyadenylic and polycytidylic acid react readily with formaldehyde, whereas the uridylic and inosinic acid polymers do not. (The latter two polymers do not carry amino-groups.) Further, the reactivity of formaldehyde with the amino-groups of the individual ribonucleic acid mononucleotides appears to be in the preferential order of adenylate, cytidylate and guanylate[8].

Formaldehyde reacts rapidly with free amino-groups, and more slowly with hydrogen-bonded amino-groups; this difference of reaction is therefore useful for the study of hydrogen-bonding through the amino-groups of the ribonucleic acid bases. Thus, the reactivity of formaldehyde and ribonucleic acid at the two temperature-levels of 25° C. and 45° C. shows a difference in rate of 19 times; a similar experiment using an appropriate mixture of mononucleotides shows a difference in rate of only 6 times[8]. Increase of temperature, therefore, besides increasing the reactivity of formaldehyde with the free amino-groups of purines and pyrimidines, also increases the extent of its reactivity with ribonucleic acid, by freeing the hydrogen-bonds involving the amino-groups of the purine and pyrimidine bases.

The concentration of formaldehyde also undoubtedly influences the type of reaction involved[8]. It seems likely that at low (0·1 per cent) formaldehyde concentrations, formaldehyde reacts by forming the monomethylol derivative ($-NH-CH_2OH$); and at higher (1·0 per cent) concentrations, the dimethylol derivative ($-N=(CH_2OH)_2$). Reaction-products of formaldehyde with the amino-groups of adenylate can also be in the form of Schiff's base[8] ($-N=CH_2$); it is probable, however, that this grouping always involves the primary production of the monomethylol derivative.

Under the conditions of my experiments, formaldehyde is added to the treatment medium containing ribonucleic acid or adenylate at a temperature of 60° C.; considerable reaction of formaldehyde with the amino-groups of ribonucleic acid and adenylate must therefore take place. Also, since a low (0·064 per cent) formaldehyde concentration is used, a predominance of monomethylol groupings is to be expected, especially as there is a high ribonucleic acid or adenylate concentration present.

The main point of interest, however, is the possible formation of a proportion of dimeric forms, resulting in the linking together of two adenylate molecules through their amino-groups ($-NH-CH_2-NH-$) by a methylene-bridge, as seen in Fig. 1. This derivative is probably formed by condensation of the monomethylol grouping on the amino-group of one adenylic acid molecule with the free amino-group of another adenylic acid molecule. It has been concluded in a study of the loss of formaldehyde from ribonucleic acid after treatment with formaldehyde[7] that two forms of formaldehyde-binding occur: a labile form (probably the methylol derivative, which is relatively quickly lost); and a more stable form, with a slowly reversible binding. A larger proportion of the formaldehyde appears to be in the labile form at early stages of the reaction, whereas at later stages more stable linkages are predominant. It is suggested[7] that the stable linkages are of the dimeric form ($-NH-CH_2-NH-$). The ease of formation of methylene-bridges by formaldehyde after reaction with proteins has already been established[10]. This type of reaction-product (Fig. 1), which is believed to be the effective metabolite under consideration, can also be formed by polymerization from the methylene derivative (Schiff's base); in this case, a polymerization structure of indefinite length could be formed by virtue of this grouping. Additional cyclic products of the type portrayed in Fig. 2 are also possible.

For purposes of discussion, the postulated metabolite will be taken as its simplest structure, namely, two adenylic acid molecules linked together by a single methylene-bridge; this will be referred to as $\overline{AA}$. It is the thesis of this discussion that the utilization of the postulated metabolite in deoxyribonucleic acid synthesis constitutes the mechanism for its mutagenic activity.

Observations on the sensitivity pattern of response of larval germ-cells to the mutagenic activity of formaldehyde[11] suggest that the sensitive period of its activity coincides with the auxocyte stage in primary spermatocyte development, namely, the protracted growth stage which precedes meiosis in the larval testis. It is also likely that this interphase period of the auxocyte stage is the time at which deoxyribonucleic acid is being synthesized.

It will be instructive at this point to consider briefly normal synthesis of deoxyribonucleic acid and the mechanism of spontaneous mutation.

Nucleic Acid Synthesis and the Mechanism of Spontaneous Mutation

In the process of deoxyribonucleic acid replication, it is assumed that each newly synthesized deoxyribonucleic acid chain is formed along a pre-existing complementary chain, as in the model for deoxyribonucleic acid proposed by Watson and Crick[12]. In this model, specificity of replication is achieved by imposing certain restrictions on the possible pairing arrangement of the four nucleotide bases: thus, adenine can only pair with thymine; and guanine only with cytosine. Either member of a given pair can occur on either chain, but its associated partner

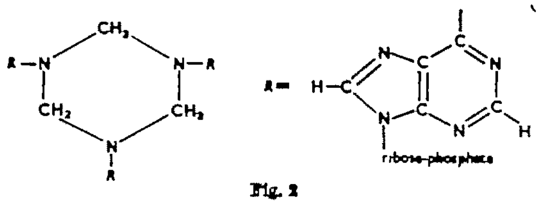

Fig. 2

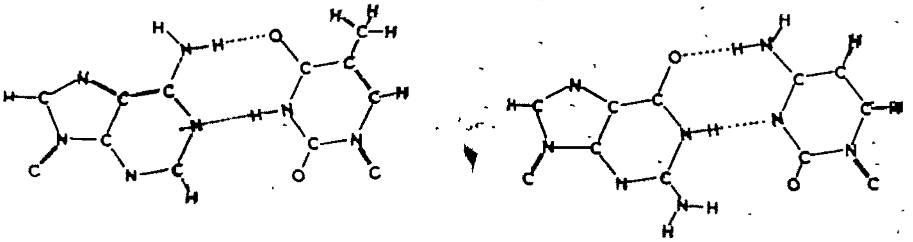

Adenine (normal amino-form) Thymine (normal keto-form) Guanine (normal keto-form) Cytosine (normal amino-form)

Adenine (rare imino-form) Cytosine (normal amino-form) Guanine (normal keto-form) Thymine (rare enol-form)

Fig. 4. Pairing of the deoxyribonucleic acid bases when a rare tautomeride of one of the bases occurs

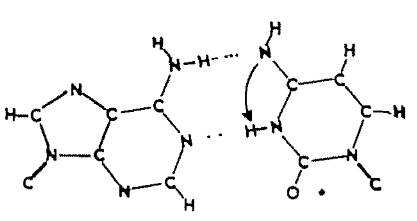
on the other chain must be the other member of the pair. This restriction is made, since although the bases can exist in a number of tautomeric forms, under physiological conditions one particular tautomeride of each base is assumed to predominate (Fig. 3).

Since the bases are tautomeric, however, it is possible for certain hydrogen atoms to change their positions occasionally, so that a base can exist in a rare tautomeric form. For example, adenine, in its normal amino-form, pairs with thymine; but if there is a tautomeric shift of one of its hydrogen atoms to give the imino-form, it can pair with cytosine (Fig. 4). The next time pairing occurs, the adenine (having resumed its more normal tautomeric form) will pair with thymine, and the cytosine will pair with guanine, thus resulting in a change in the sequence of bases. (A tautomeric shift in thymine whereby it can pair by mistake with guanine, and lead to a similar change in base sequence, is illustrated in Fig. 4.) This change in the sequence of bases by mistaken pairing, due to the presence of a rare tautomeride of one of the bases at the time of deoxyribonucleic acid replication, is believed to be the mechanism of spontaneous mutation[12].

It is now possible to consider the utilization of the postulated metabolite ($\overline{AA}$) in deoxyribonucleic acid synthesis, and the mechanism of its mutagenic activity. This metabolite possesses the correct hydrogen-bonding properties for base-pairing in the Watson and Crick model for deoxyribonucleic acid[12]; and it is interesting to note that the length of the methylene-bridge (3·7 Å.) approximates closely with the distance of 3·4 Å. between adjacent nucleotides of the same deoxyribonucleic acid chain.

Utilization of the Postulated Metabolite in Deoxyribonucleic Acid Synthesis; a Mechanism for its Mutagenic Activity

The presence of thymine (T) and cytosine (C) as adjacent nucleotides on the pre-existing deoxyribonucleic acid chain is the most obvious sequence by which the metabolite ($\overline{AA}$) could be incorporated into replicating deoxyribonucleic acid, resulting in a change in the base sequence. A prerequisite for forced pairing is that the first adenylate incorporated pairs normally, that is, with thymine; and the other adenylate, which is linked to it, thus forms a pairing mistake with cytosine. This pairing mistake could be accommodated either by tautomeric shift of one of the hydrogen atoms of the adenylate molecule (Fig. 4), or by tautomeric shift in the cytosine with which it is attempting to pair (Fig. 5). In subsequent replications, the incorporated metabolite ($\overline{AA}$) attaches to itself its normal complementary bases (TT), thus changing the original sequence, as illustrated by example in Fig. 6, from $GCATCAG$ to $GCATTAG$. Once the change in base sequence has been initiated on incorporation of $\overline{AA}$ into replicating deoxyribonucleic acid, the methylene-bridge linkage is no longer necessary, since the mistake is fixed. It should be noted that besides needing an appropriate sequence for activity, the $\overline{AA}$ metabolite could miss an opportunity to produce a change in sequence



Adenine (normal amino-form) Cytosine (rare imino-form)

Fig. 5. Pairing between adenine and cytosine when cytosine is in its rare tautomeric form

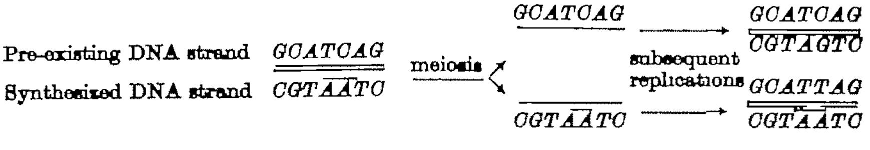


Fig. 6. Mechanism by which the postulated metabolite ($\overline{AA}$) can produce a change in the base sequence of deoxyribonucleic acid

by being initially incorporated at a *TT* sequence. Related mechanisms by which mutagenic purine and pyrimidine analogues can produce a change in the sequence of bases by their incorporation into bacteriophage deoxyribonucleic acid have been suggested by Freese[13].

During the preceding discussion, the instance where two adenylate molecules only are linked together has been considered; but larger metabolites are possible. When adenylate molecules are free in the medium, a metabolite of indefinite length could theoretically be formed. However, in the case of larger metabolites being formed by reaction of formaldehyde with ribonucleic acid, a restriction of their size would be expected, since the span of the methylene-bridge only allows linkage of adjacent adenylate molecules, which is limited by the sequence of bases along the ribonucleic acid chain. Such metabolites as are formed within ribonucleic acid would afterwards be liberated by hydrolysis of the ribonucleic acid sugar–phosphate bonds during breakdown of the ribonucleic acid into its constituent nucleotides in the gut of the larvæ; methylene-bridge linkages in proteins have been shown to be resistant to acid hydrolysis[10].

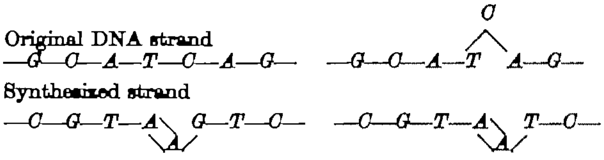
Larger metabolites are less easily incorporated into a necessary base sequence of deoxyribonucleic acid for effective utilization; for example, $\overline{AAA}$ would probably need a base sequence of *TTC*, *TCT*, or perhaps *TCC*, to initiate a change in base sequence.

In the present system, adenylate is the only ribonucleic acid base nucleotide utilized to any extent. Furthermore, as previously noted, the reactivity of formaldehyde with the amino-groups of the individual ribonucleic acid mononucleotides appears to be in the preferential order of adenylate, cytidylate and guanylate. Therefore, although other effective combinations of linked bases are theoretically possible, for example, $\overline{AC}$, $\overline{CC}$, $\overline{GG}$, and others, the $\overline{AA}$ metabolite (and perhaps an $\overline{AC}$ metabolite), would be expected to be the only significant metabolite in this system. Further, the possible utilization of a $\overline{UU}$ metabolite cannot be completely excluded in these experiments (Table 1), since the *Drosophila* stock used has a partial requirement for cytidylate[4]. Thus, the formation of appropriately linked nucleotide molecules of the type described may represent, *a priori*, a way by which specific mutagens and potential cancer chemotherapeutic agents can be constructed.

A recent investigation[14] has examined the possibilities whereby non-complementary bases can be accommodated within the two-stranded helical framework of polyribonucleotides and deoxyribonucleic acids. The authors studied the effects of varying proportions of non-complementary bases incorporated into pairs of complementary polyribonucleotides which are known to form two-stranded helices like deoxyribonucleic acid. Mixing curves were used to study the quantitative aspects of the interaction of polyadenylate (poly *A*) or polyuridylate (poly *U*) with a series of single-stranded poly *AU* copolymers. On the results of these experiments, it is concluded that non-complementary nucleotide residues in the copolymer do not remain within the helix, but loop out of the helix to allow hydrogen-bonded base pairing of subsequent regions of nucleotides which are in register. This observation is compatible with model building on the Pauling–Corey space-filling nucleotide model, where non-complementary nucleotide residues can be rotated out of the helix to allow a continuity of base pairs along its entire length. This model leaves the non-complementary base pointing radially out of the helix axis, and allows an adjacent nucleotide residue to move into the vacancy created, without stress. In addition, similar loops containing two, three or more nucleotides are also possible. In all cases, the regularity of the helix in the vicinity of the loop is unaffected, both the 3·4 Å. separation and 36° translation of successive nucleotides being maintained.

In view of the similarity of essential structure between the poly $(A + U)$ helix and deoxyribonucleic acid, it seems likely that any base pair mismatchings arising during deoxyribonucleic acid synthesis could also be accommodated by loop formation[14].

The authors discuss hypothetical models for the origin of point mutation, and, translating their models to fit the present discussion of the mutagenic mode of action of the postulated $\overline{AA}$ metabolite, the following mechanisms are suggested:



The original DNA strand remains identical in each case.

Adenine, as seen in Tables 1 and 2, has little or no capacity for mediating formaldehyde-induced mutagenesis. Formaldehyde should be able to link together two adenine molecules, in the same way as postulated for adenylate, but its free amino-group at the 9-position of the purine ring may be blocked by additional reaction with formaldehyde, thus preventing the ribose sugar attachment. This condition would be expected to debar the utilization of adenine in nucleic acid synthesis; and this is supported by the fact that I have now shown (unpublished results) that adenosine is as effective as adenylate in the mediation of formaldehyde-induced mutagenesis.

In should be noted in conclusion that the results and interpretation detailed here are entirely compatible with observations made with these test-substances on a formaldehyde-containing yeast-glucose treatment medium (unpublished work).

My acknowledgments are due to the Medical Research Council for financial support of this work, and to Prof. C. H. Waddington for supplying the laboratory facilities.

LETTERS TO THE EDITORS

ASTRONOMY

Roughness of the Moon as a Radar Reflector

In a recent communication[1] Hughes has suggested that the law of scattering of radio waves by the lunar surface is consistent with scattering by a rough surface which has irregularities much greater than the radio wave-length, and such that the root mean square value of the slope is about 1 in 20, or 3°. The law of scattering as a function of angle of incidence which, on this model, would be the same as the distribution of the slope of the irregular surface, was found from radar observations to be given by:

$$\sigma = \sigma_0 \exp\{-10\theta\}$$

where σ is the effective scattering area and θ the angle of incidence.

It is of interest to compare this with the distribution of the slope of the lunar surface as determined optically. Fujinami, Ina and Kawai[2] have made photometric measurements of the profile of the Moon's silhouette, as observed during a partial eclipse. Measurements of the elevation of the lunar surface in seconds of arc were made for every degree around the limb. It is a simple matter to obtain a value for the slope of the lunar surface from each successive pair of readings. The distribution of these values, without regard to sign, is shown as a histogram in Fig. 1. The exponential law $\exp(-10\theta)$ is shown as a dotted line for comparison. It will be seen that there is close agreement except for angles less than 1°. (The law proposed by Hughes was stated to apply over the range 3–14°.) The root mean square value of the slope, as determined from the optical measurements, is 3·3°.

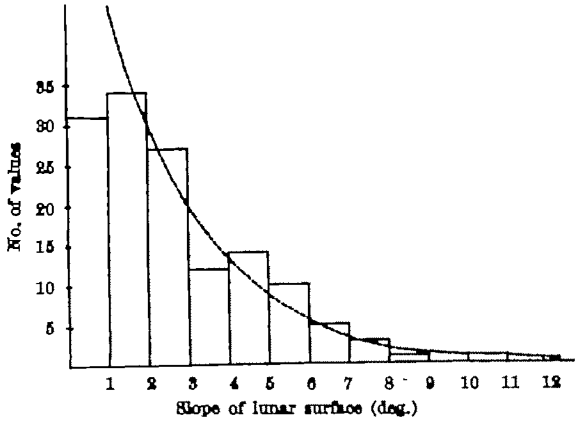

Fig. 1. The distribution of the values of the slope of the lunar surface as determined from the optical measurements of Fujinami, Ina and Kawai. The dotted line is the exponential function $\exp(-10\theta)$

This agreement is interesting; but it is, perhaps, surprising, because the optical measurements refer only to structure with a horizontal scale larger than about 30 km. The lunar surface could contain structure of a smaller scale, which would not be resolved optically, but which was larger than the radio wave-length. If the root mean square value of the slope of this smaller-scale structure were comparable with or larger than 3°, the overall distribution of the slope would extend to angles too large to fit the radio observations. The fact that agreement is obtained when only structure larger than 30 km. is considered suggests that the smaller structure, if it exists, has a root mean square value of slope considerably less than 3°.

GEOPHYSICS

Evaluation of the Second, Fourth and Sixth Harmonics in the Earth's Gravitational Potential

In an article[1] in *Nature* in 1958, it was explained how the rate of rotation of the orbital plane of an Earth satellite (the rate of regression of the nodes) could be used to evaluate the even harmonics in the Earth's gravitational potential U. At an exterior point distant r from the Earth's centre and having co-latitude θ, U may be expressed in terms of Legendre polynomials P_n as:

$$U = \frac{GM}{r}\left\{1 - \sum_{n=2}^{\infty} J_n \left(\frac{R}{r}\right)^n P_n(\cos\theta)\right\} \quad (1)$$

where G is the gravitational constant, M the mass of the Earth, R its equatorial radius, and the J_n are constants to be determined. J_1 is zero if the equator is chosen to pass through the Earth's centre of mass. The motion of a satellite in the gravitational field specified by equation (1) has been investigated theoretically[2-4], and the rate of rotation of the orbital plane, $\dot{\Omega}$, may in principle be expressed in the form:

$$\dot{\Omega} = \sum_{n=2}^{\infty} J_n F_n + \sum_{m=2}^{\infty} \sum_{n=2}^{\infty} J_m J_n F_{mn} + \ldots \quad (2)$$

where the F_n and F_{mn} are functions of the orbital elements. Since J_2 is of order 10^{-3}, the J_n are of order 10^{-6} when $n > 2$, and the F_n are of the same order as the F_{mn}, only the J_2^2 term in the second series in equation (2) need be considered, and even in that term an approximate value of J_2 is adequate. Thus each observed value of $\dot{\Omega}$ provides one linear relation between the J_n, and observed values from k satellites provide k simultaneous equations between the J_n. These equations are not ill-conditioned if the k orbits differ widely enough. It happens that the odd-numbered J_n have little effect on $\dot{\Omega}$, and the available values[5] for J_3 and J_5, namely:

$$\left.\begin{aligned} J_3 &= (-2{\cdot}4 \pm 0{\cdot}3) \times 10^{-6} \\ J_5 &= (-0{\cdot}1 \pm 0{\cdot}1) \times 10^{-6} \end{aligned}\right\} \quad (3)$$

can be substituted into equation (2) without introducing significant error. Thus k satellites with widely different orbits—and, in particular, with widely differing orbital inclinations—will yield values of $J_2, J_4, \ldots J_{2k}$ if we are prepared to assume that the contributions of $J_3, J_5 \ldots$ and of $J_{2k+2}, J_{2k+4}, \ldots$ are negligible.

This process has been applied to the orbits of the satellites *Sputnik* 2 (1957β, inclination $i = 65°$), *Vanguard* 1 (1958β2, $i = 34°$) and *Explorer* 7 (1959ι1, $i = 51°$), and the following values of J_2, J_4 and J_6 have been obtained:

$$\left.\begin{aligned} J_2 &= (1082 \cdot 79 \pm 0 \cdot 15) \times 10^{-6} \\ J_4 &= (-1 \cdot 4 \pm 0 \cdot 2) \times 10^{-6} \\ J_6 &= (0 \cdot 9 \pm 0 \cdot 8) \times 10^{-6} \end{aligned}\right\} \qquad (4)$$

The errors quoted are standard deviations due to observational error. In deriving these values, the effect of atmospheric rotation on $\dot{\Omega}$ and the effects of the Sun and Moon were taken into account. It is possible that errors larger than those quoted in equation (4) might be caused by the neglect of J_8, J_{10}, etc.; but it is significant that the above set of values is consistent with that derived[6] using the *Explorer* 4 satellite (1958ε) instead of *Explorer* 7, and with the values of J_2 and J_4 obtained by O'Keefe *et al.*[5] using different observational information and ignoring J_6. Thus there is reason for hoping that the errors due to the neglected higher J_n will not much exceed the errors quoted in equation (4).

If the Earth's flattening f is defined as the difference between the equatorial and polar diameters, divided by the equatorial diameter, and the meridional section is taken as elliptic, as has been customary in the past, the new value of J_2 gives $1/f = 298 \cdot 24 \pm 0 \cdot 02$, as compared with the value of 297·1 which was most generally accepted[7] before the advent of satellites.

A fuller account of this work is being published elsewhere.

Oscillatory Character of Amplitude Curves for Seismic Body Waves

THE importance of studying the amplitudes of seismic body waves in relation to the structure of the Earth's mantle has been emphasized by several authors[1,2]. In previous investigations[3-6], however, only general features of amplitude curves in limited distance intervals were given. Combining observations of four Middle European seismic stations—Prague, Jena, Collmberg and Potsdam—we obtained a sufficient set of homogeneous data to derive the fine structure of amplitude curves for P-, PP- and S-waves.

Maximum ground amplitudes A in μ and periods T in sec. for individual waves could be estimated by special analysis of 275 well-recorded earthquakes. Using corresponding station corrections[7], the local effects on amplitudes of body waves were eliminated. The eventual effects of the earthquake mechanism were considerably minimized by the proximity of the stations. The number of observations was as follows: 501 for PH, 166 for PV, 520 for SH, all in the range of 10°–100°, and 258 for PPH in the range of 15°–160°. Epicentral distances Δ were computed from *ISS* parameters, and from 1950 from *BCIS* or *USCGS* parameters, respectively.

Introducing:

$$A^*_i = \log A_i/T_i - M_i \qquad (1)$$

for $i = PH, PV, PPH, SH$, where the magnitudes:

$$M_i = \frac{1}{n} \sum_{j=1}^{n} M_i^j \qquad (2)$$

for j = Prague, Jena, Collmberg, Potsdam were determined on the basis of the second approximation of the magnitude calibrating functions for body waves[7], we can take the graphical representation of the dependence (A^*_i, Δ) as the amplitude curve for the corresponding wave. The whole set of observations for an individual wave was divided into natural intervals, which were represented by their centres of gravity (large crosses in Fig. 1). Through these representative points the amplitude curve was then drafted allowing for the tendency of detailed distribution of the observations. Thus the fine structure of amplitude curves could be investigated with a considerable degree of certainty.

Two partial sections of amplitude curves with the points of observation and corresponding representative points for horizontal components of P- and PP-waves in the distance range near the '20° discontinuity' are shown in Fig. 1. The oscillatory character of the amplitude curves can be clearly seen. This

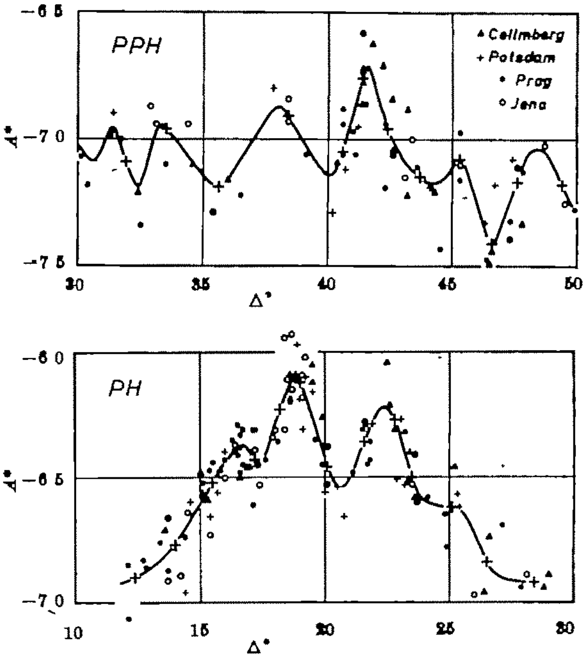

Fig. 1. Sections of amplitude curves for horizontal component of P- and PP-waves. A^*, Reduced amplitude according to equation (1); Δ, epicentral distance in degrees; large +, representative points of natural intervals

phenomenon was also found for other waves being investigated in several distance ranges.

A similar oscillatory tendency of the amplitude curve for P-waves can be observed by detailed investigation of the seismic data of underground nuclear explosions published recently[8]; the number of observations in this case, however, is insufficient for detailed conclusions. In comparison with amplitude curves reported in this communication these observations seem to show regional influences due to the probably regional structure of the upper mantle[8,9]. The oscillations observed in this distance range are evidently connected with the surface field of waves diffracted at the asthenosphere low-velocity layer[10].

A more detailed account of this work will be published in the Gerlands Beiträge zur Geophysik.

PHYSICS

Speed of the Superconducting-Normal Transition in Tin Films

We have carried out some experiments to study the rate at which resistance is restored in a superconducting tin film by the application of a magnetic field above the critical value. No direct experiment of this kind has previously been reported, although Woodford and Feucht[1], using a radiofrequency method, inferred that the transition in an evaporated film of an unspecified metal probably occurred in less than 10^{-8} sec. The question is of some importance both from a fundamental point of view and in determining the lower limit of the switching time of superconducting circuit devices such as the cryotron.

In our experiments, tin films with the characteristic 'dumb-bell' shape were evaporated on to glass slides, the central region of the films being approximately 1 cm. long, 100–400μ wide and 1000 Å. thick. The slides fitted closely into a small solenoid (1 cm. long × 0·3 cm. × 0·1 cm.) which produced a magnetic field of 29·5 oersteds/amp. The solenoid had an inductance of 0·3 μH. and was fed through a 50 Ω coaxial cable with a rectangular current pulse which had a rise time of 10 mμsec., a length of 0·3 μsec. and a maximum amplitude of 2 amp. Experiments were normally carried out about 0·1 deg. K. below the transition temperature where the critical field was ≃ 150 oersteds. The pulsed field provided by the solenoid was superposed on a steady field supplied by an electromagnet. The restoration of resistance was observed by displaying on an oscilloscope, after suitable amplification, the potential difference across the film produced by a constant current, the value of this current being limited to ∼ 1 m.amp. by the Joule heating in the film while in the normal state. The normal resistance of the films was in the region of a few ohms so that the signals had an amplitude of a few millivolts.

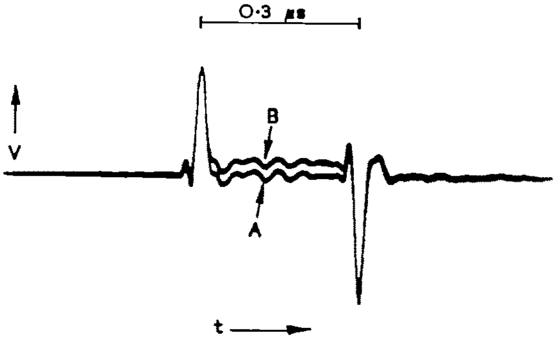

Fig. 1. Restoration of resistance in a tin film of width 250μ, thickness 1000 Å. and length 1 cm. Trace *A*, zero current through the film. Trace *B*, 1 m.amp. through the film

Fig. 1 shows two superposed oscilloscope traces representing the potential difference across a typical film with and without a direct current through it. The positive and negative spikes are due to the inductive electromotive force which arises at the beginning and end of the field pulse. No delay is observable between the instant at which the pulsed magnetic field becomes constant and the restoration of resistance, and since the two traces are parallel there is no evidence of a progressive growth of resistance; there is also no evidence of any resistance remaining after the end of the pulse. This behaviour was independent of the amount by which the pulsed field exceeded the threshold value. From Fig. 1 we deduce that the transition from the superconducting to the normal state and vice versa takes place within the overall resolution of 15 mμsec., which implies that the relaxation time for the destruction of superconductivity is less than ∼ 10^{-8} sec. It would require a much more complicated apparatus to lower this limit significantly.

Strengths of Acid-etched Glass Rods

The low breaking strength of normal glasses is usually regarded as being due to surface imperfections, and previous workers, particularly Greene[1], have directed attention to the increase in strength which occurs when the glass surface is etched with hydrofluoric acid. By measuring the rate at which a

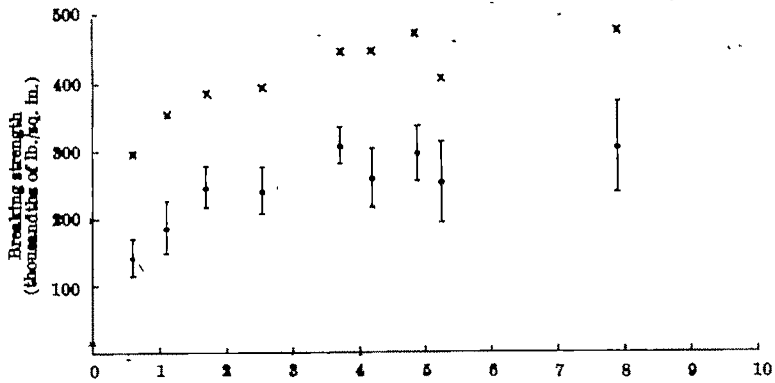

Fig. 1. Breaking strength as a function of depth of material removed from the surface. ×, Highest strength value in one group of rods; ●, mean strength and 95 per cent confidence limits for one group of rods

particular etching solution removes material from a glass surface it is possible to study the strength of etched specimens as a function of the depth of material removed from the surface. Such a study may give some information about the size and nature of the surface imperfections.

Commercially available soda-glass rods, of 6–8 mm. diameter, have been etched and broken in four point bending over a constant bending moment span of 1 in. The rod diameters and loads at fracture were measured and the breaking stresses calculated using the simple bending formula. Groups of rods (containing 16–32 rods) were given different periods of etching, and the depth of material removed from the surface of the rods was calculated for each group.

The variation of the mean breaking strength of these groups of rods, with depth of material removed from the surface, is shown in Fig. 1. Also shown on Fig. 1 are the 95 per cent confidence limits on the mean strength and the highest strength value recorded in each group of rods. Fig. 2 is a histogram comparing the distribution of breaking stresses for a group of rods which have been etched for 40 min. with that for unetched rods. The maximum strengths obtained with these bulk glass specimens are in the region 450,000–500,000 lb./sq. in. and closely approach the value obtained by Thomas[2] for fine glass fibres.

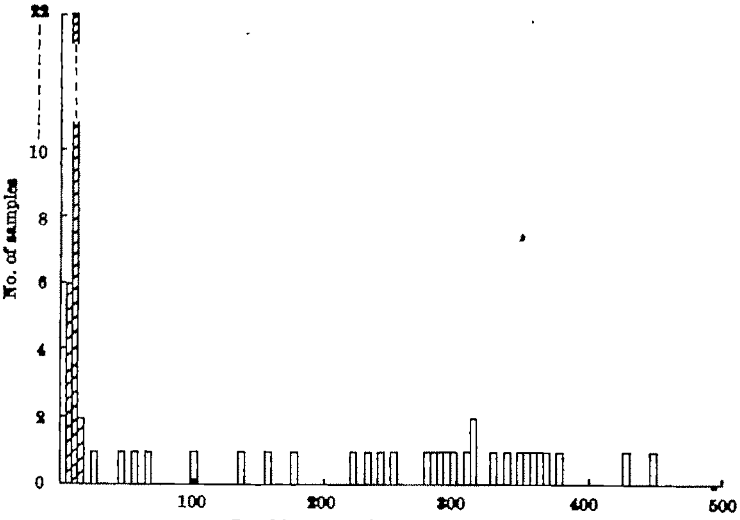

Fig. 2. Frequency of results as a function of breaking strength for etched (unshaded) and unetched (shaded) rods. The former were etched for 40 min.; depth removed from surface = 4.2 × 10^{-4} cm.

The glass rod used in these experiments had the following approximate composition by weight (percentages): SiO_2, 69; Na_2O, 16; CaO, 4; Al_2O_3, 3; MgO, 3.

The etching solution contained about 15 per cent hydrofluoric acid, 15 per cent sulphuric acid by weight and the remainder water.

Experiments are being continued to determine the effect on these results of varying the concentration, temperature and nature of the etchant; and of changing the thermal history, size and composition of the glass.

Stimulated Optical Radiation in Ruby

Schawlow and Townes[1] have proposed a technique for the generation of very monochromatic radiation in the infra-red optical region of the spectrum using an alkali vapour as the active medium. Javan[2] and Sanders[3] have discussed proposals involving electron-excited gaseous systems. In this laboratory an optical pumping technique has been successfully applied to a fluorescent solid resulting in the attainment of negative temperatures and stimulated optical emission at a wave-length of 6943 Å.; the active material used was ruby (chromium in corundum).

A simplified energy-level diagram for triply ionized chromium in this crystal is shown in Fig. 1. When this material is irradiated with energy at a wave-length of about 5500 Å., chromium ions are excited to the $^4F_2$ state and then quickly lose some of their excitation energy through non-radiative transitions to the ^2E state[4]. This state then slowly decays by spontaneously emitting a sharp doublet the components of which at 300° K. are at 6943 Å. and 6929 Å. (Fig. 2*a*). Under very intense excitation the population of this metastable state (^2E) can become greater than that of the ground-state; this is the condition for negative temperatures and consequently amplification via stimulated emission.

To demonstrate the above effect a ruby crystal of 1-cm. dimensions coated on two parallel faces with silver was irradiated by a high-power flash lamp;

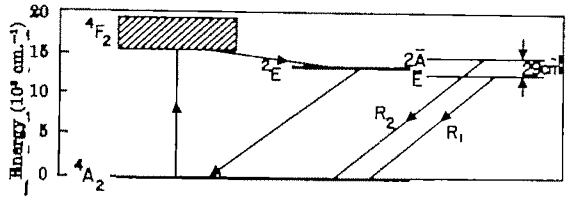

Fig. 1. Energy-level diagram of Cr^{3+} in corundum, showing pertinent processes

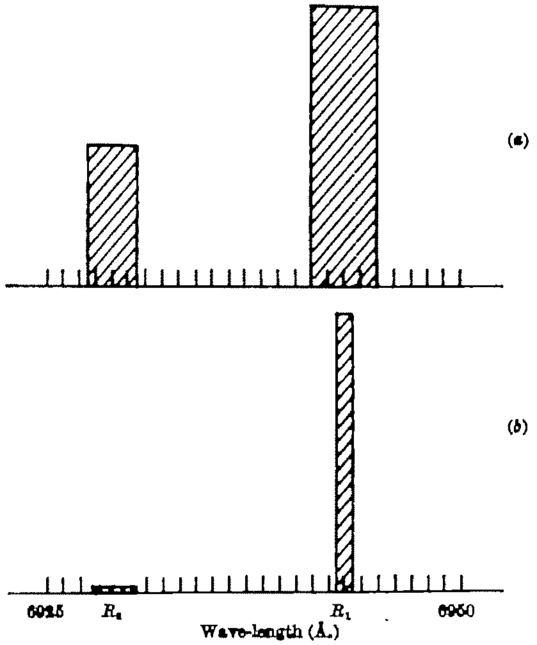

Fig. 2. Emission spectrum of ruby: a, low-power excitation; b, high-power excitation

the emission spectrum obtained under these conditions is shown in Fig. 2b. These results can be explained on the basis that negative temperatures were produced and regenerative amplification ensued. I expect, in principle, a considerably greater (~ 10^3) reduction in line width when mode selection techniques are used[1].

I gratefully acknowledge helpful discussions with G. Birnbaum, R. W. Hellwarth, L. C. Levitt, and R. A. Satten and am indebted to I. J. D'Haenens and C. K. Asawa for technical assistance in obtaining the measurements.

METALLURGY

A Simple Method of investigating the Creep of Metals under Simple Shear

DR. K. H. JOLLIFFE and I[1] have investigated the creep of metals under simple shear by the use of a disk of the metal in question in which is cut a concentric circular annulus, the metal external to the annulus being securely gripped, while that internal to the annulus is subjected to a constant torque. We have shown that the behaviour of the metal in these circumstances is in many ways simpler and more informative than that exhibited by wires or rods under tension.

From the point of view of the industrial study of creep, the method has the disadvantage that the specimens are somewhat troublesome to prepare and measure. To get over this difficulty I have devised a method in which the specimen has the form shown in Fig. 1. In the plate *ABCD* (Fig. 1a) are cut rectangular grooves *MNOP*, *QRST*, as shown in cross-section in Fig. 1b. The metal *ABNM*, *TSCD* is securely held, and a force *F* applied to the metal *PORQ* in a direction parallel to the grooves. Under these conditions the shear stress distribution in the rectangular plates *MNOP*, *QRST* is not strictly uniform, as it is in the disk method, which is clear from the fact that the shear stress over the free ends must be zero. The distribution has been worked out by me[2] and by C. E. Inglis[3].

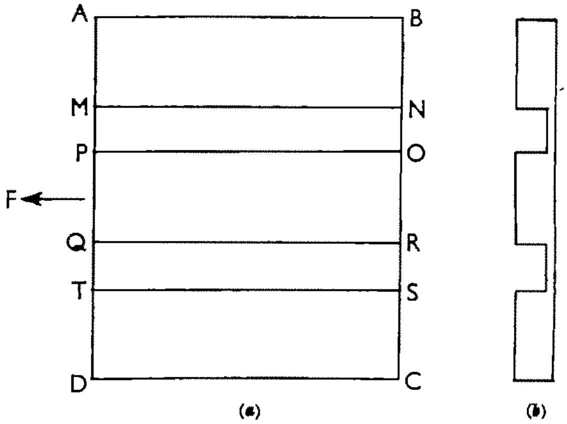

Fig. 1

Mr. D. B. Gilding has been working under my direction on the best form of the plate and has established that if the ratio of *MN* to *NO* is in the region of 7, the results on creep obtained with the disposition described correspond closely to those obtained by the method of Andrade and Jolliffe[1]. It seems possible that the new method may be of use in further investigations of creep and may also have applications to the problem of fatigue.

An Improvement in the Ductility of Beryllium at High Temperatures

THE outstanding problem in beryllium metallurgy is the lack of ductility exhibited by the metal, both at room temperature and at elevated temperatures. At room temperature, brittleness can be attributed to the ease of cleavage of basal planes of the hexagonal lattice, and to the high yield-strength of the prismatic planes, while at temperatures above 400° C., intergranular failure predominates. A ductility maximum occurs at intermediate temperatures depending on the strain-rate used, tensile specimens failing with

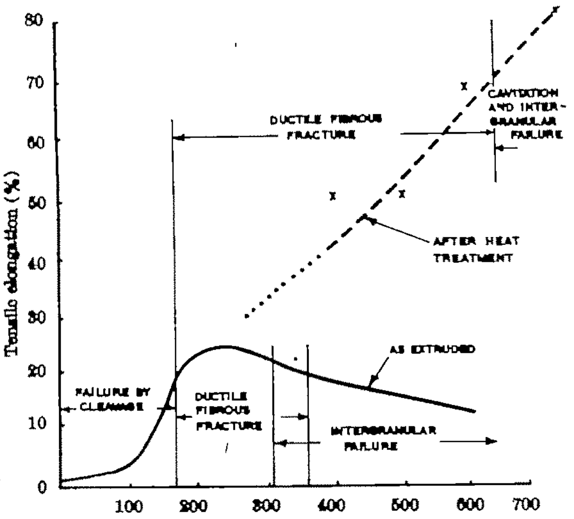

Fig. 1. Vacuum cast, pebble beryllium extruded at 1,050° C. 44 : 1 reduction

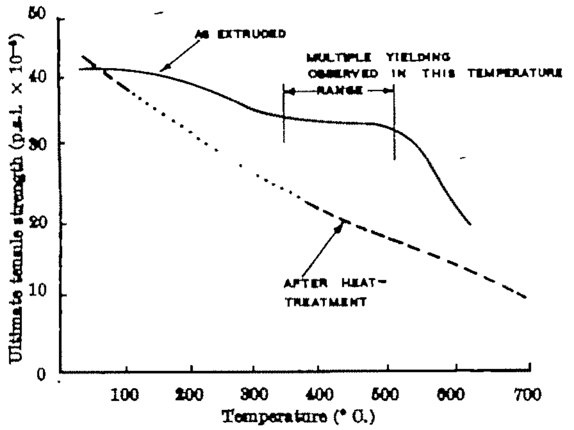

Fig. 2. Thermally reduced beryllium, vacuum cast and extruded at 1,050° C. 44 : 1 reduction

a ductile, fibrous fracture between 200° and 400° C. These fracture modes overlap, and two or more types of failure may be seen in any one tensile specimen.

Some increase in low-temperature ductility can be obtained by fabrication techniques which develop a texture in which the basal planes are oriented parallel to direction of working, so that loads applied in this direction exert little normal stress on basal cleavage planes. Additional resistance to cleavage is achieved by a reduction of grain size. Little has been done in the past to reduce the extent of intergranular failure, which becomes the predominant fracture mode in extruded beryllium rods as the temperature is increased above 400° C. Recent work at the Atomic Weapons Research Establishment, however, indicates that the temperature at which intergranular failure occurs can be raised by several hundred degrees by heat treating material of a suitable composition.

Fig. 1 shows the extent of the improvement in ductility that has been achieved in extruded ingot bar, fabricated from thermally reduced metal, after a heat treatment which involved heating the bar at 780° C. for 120 hr. followed by slowly cooling to room temperature over a further 120 hr. This treatment, which was insufficient to promote grain growth, apparently resulted in the precipitation of certain impurities from metastable solid solution.

Some reduction in strength also ensued from this treatment, as can be seen from a comparison of the 'as-received' and 'heat-treated' curves in Fig. 2. Of greater significance is the fact that the strength 'plateau', evident in tensile tests on the as-extruded material, between 350° and 500° C., was completely removed by the annealing treatment. This plateau was associated with multiple yielding phenomena, which can be symptomatic of the diffusion of solute impurities during the tensile test. No multiple yielding was found after the annealing treatment, and it is proposed that the solute elements concerned were precipitated, either during the treatment at 780° C. or during the subsequent equilibrium cooling. The reversibility of this precipitation treatment has been demonstrated in hot-hardness tests, re-solution appearing to occur at temperatures between 800° and 1,000° C.

The increase in ductility was associated with the disappearance of the intergranular type of failure usually inherent in beryllium at temperatures above 400° C. Comparative microstructures of the fracture modes in as-extruded and heat-treated specimens, tested at 600° C., are shown in Fig. 3.

The phenomenon was not associated merely with a softening of the matrix during annealing. A second bar of material, prepared in an identical way from purer electrolytic flake material, revealed little amelioration of tensile ductility after heat treatment as can be seen from Fig. 4. Furthermore, the hot

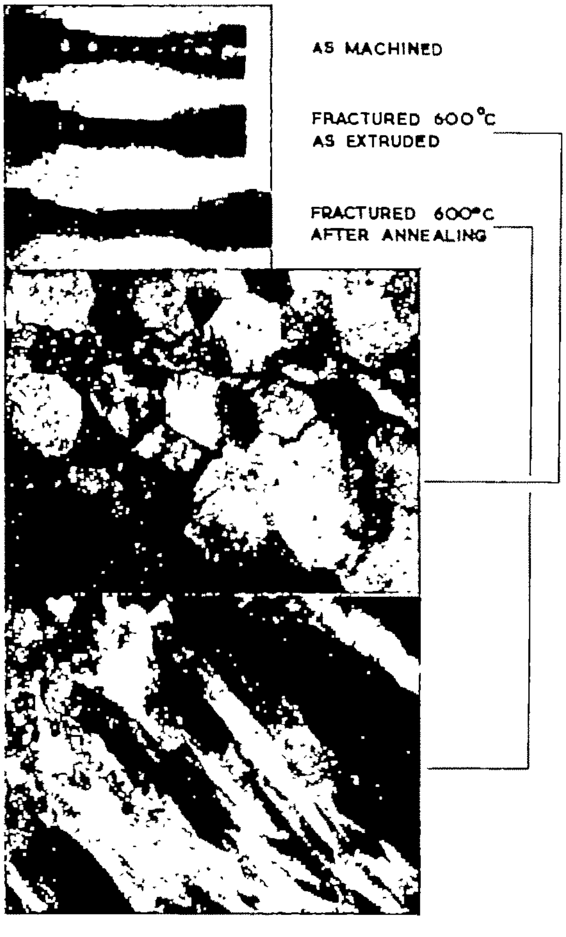

Fig. 3. (× c. 60)

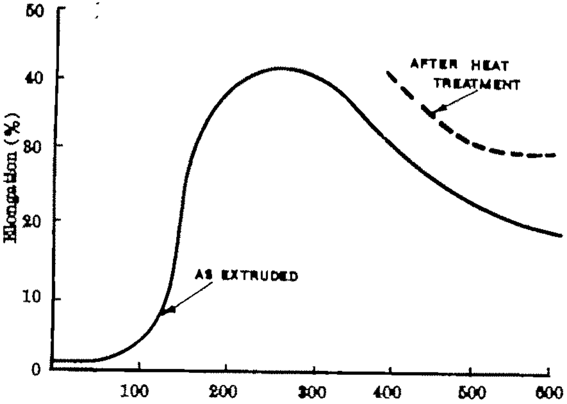

Fig. 4. Vacuum cast, electrolytic flake beryllium extruded at 1,050° C. 44 : 1 reduction

hardness characteristics of this material in the as-extruded condition were coincident with those of heat-treated thermally reduced material, and were unaffected by subsequent heat treatment. No multiple yielding was observed in this bar, even in the as-extruded state. The matrix properties of the two materials would appear to be similar after heat treatment, yet ductility is associated only with the thermally reduced material.

These, and other metallographic observations on the migration of impurities to grain boundaries in the more impure, thermally reduced metal, suggest that a specific impurity phase(s) in the more impure material artificially strengthens the boundaries at high temperatures, possibly by a keying action which prevents the boundaries shearing. This phase(s), which is either absent, or present to a smaller extent in the purer, electrolytic material, appears to migrate preferentially to the grain boundary region during the heat treatment.

This phenomenon is obviously of great importance in the metallurgy of beryllium at temperatures between 500° and 600° C., that is, within the temperature range where beryllium is to be used in nuclear reactors of the A.G.R. type, and indicates the possibility of alloying to improve the ductility at these temperatures.

Hexagonal Modification of Black Chromium Electro-deposit

The formation of a hexagonal modification of an electro-deposited chromium has been discussed since the first announcement was made. In 1935, L. Wright *et al.*[1] determined the conditions for the production of the hexagonal form from chromic acid baths, and recently C. A. Snavely[2] fully examined the structural characteristics of the electro-deposited chromium from chromic acid baths containing sulphate ion.

The hexagonal modification of the black chromium electro-deposit has not been reported since the first report of black chromium was made by Siemense and Halske[3] in 1933.

The mixed crystal (hexagonal-closest-packed + body-centred cubic) was found in the black chromium electro-deposit obtained from the new bath containing chromic acid, acetic acid and urea. We were interested in this phenomenon and studied the formation of the hexagonal modification of the black chromium electro-deposit.

The baths used in this experiment were as follows: (1) chromic acid 3 *M*, acetic acid 0·05 *M* [3]; (2) chromic acid 3 *M*, acetic acid 0·05 *M*, urea 0·05 *M* [4]; (3) chromic acid 200 gm./l., glacial acetic acid 6 ml./l., nickel chloride 20 gm./l., vanadium oxide 7·1 gm./l. [5]. Precautions were taken to remove a sulphate ion contained in the chromic acid reagent. The specimens were made by electro-deposition on a copper wire at a current density of 100 amp./sq. dm. and at 15 ± 1° C. The time of electrolysis was about 3 hr. X-ray examination was made immediately after the end of electrolysis.

The X-ray diffraction analysis indicated that the structures of the electro-deposits obtained under the above conditions consisted of the mixed crystal —hexagonal - closest - packed + body - centred cube. The typical Debye–Scherrer photograph of the mixed crystals is shown in Fig. 1.

Wright *et al.*[1] stated that the factor influencing the formation of the hexagonal modification was the percentage of chromium existing in the cation in reduced chromic acid solutions. In the black chromium plating baths the mixed crystals were obtained under the conditions mentioned above in the absence of the trivalent chromium.

During the repeated electrolysis the pure hexagonal form appeared in the deposit which was electro-deposited for 14¼ hr. from the bath[2] (Fig. 2).

The effects of the bath temperature, the concentration of chromic ion and urea, and the time of electrolysis on the formation of the pure hexagonal structure were examined. However, it could not be determined which factor was responsible for the formation of the pure hexagonal structure.

The change of the structure of the mixed crystal to the body-centred cubic has been reported by several authors[3,4]. In this experiment, the mixed

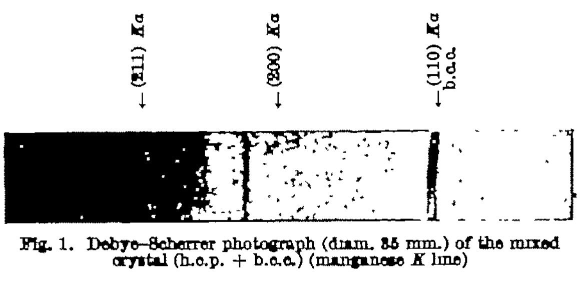

Fig. 1. Debye–Scherrer photograph (diam. 35 mm.) of the mixed crystal (h.c.p. + b.c.c.) (manganese *K* line)

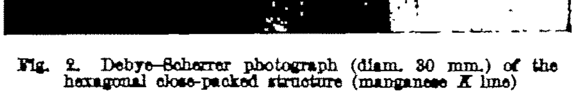

Fig. 2. Debye–Scherrer photograph (diam. 30 mm.) of the hexagonal close-packed structure (manganese *K* line)

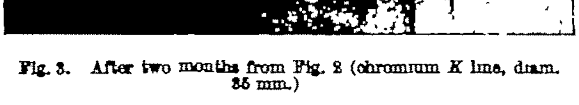

Fig. 3. After two months from Fig. 2 (chromium *K* line, diam. 35 mm.)

crystals changed to the body-centred cubic structure from time to time. On the contrary, the pure or almost pure hexagonal crystal did not change even after two months from the end of the electrolysis (Fig. 3). When this deposit was treated in a hydrogen atmosphere at 150° C., the structure changed to the body-centred cubic crystal.

C. A. Snavely[2] thought that there is a relation between the structure of the electro-deposited chromium and the *p*H of the cathode film during electrolysis. It is suggested from the above results that the *p*H of the cathode film during the electrolysis in the black chromium baths was higher.

We wish to thank Prof. Y. Shimomura and Mr. M. Kojima for the X-ray diffraction analysis.

GEOLOGY

Stability of Epidote Minerals

A NUMBER of silicate minerals have proved difficult to synthesize by the commonly employed methods involving hydrothermal crystallization of glasses or reactive oxide mixes of suitable composition. Failure to synthesize a phase may be caused by the experimental conditions not being within the region where the phase is thermodynamically stable. But, in some cases, failure simply reflects a large nucleation barrier to the formation of the stable phase so that metastable phases which nucleate with ease form, and may persist indefinitely. Several workers[1–3] have considered this problem in relation to the epidote minerals, and the consistent failure of low-pressure synthesis could indicate that these phases may be stable only under relatively high-pressure conditions. Geological occurrence does not entirely support this proposition. The results presented here indicate that with these minerals nucleation is a sluggish process at low pressures, and if this step is by-passed, growth is readily achieved from the phases which normally form in synthesis. This sluggish nucleation is possibly related to the structure of the minerals.

Proof that the epidote minerals (zoisite, clinozoisite, epidote) are stable relative to the phases commonly formed in synthesis from their composition has been approached as follows. When zoisite is thermally decomposed at one atmosphere, reaction proceeds according to the reaction:

$$\underset{\text{zoisite}}{2Ca_2Al_3Si_3O_{12}(OH)} \rightarrow \underset{\text{anorthite}}{2CaAl_2Si_2O_8} + \underset{\text{wollastonite}}{CaSiO_3} + \underset{\text{gehlenite}}{CaAl_2SiO_7} + H_2O$$

Similar reactions can be written for other members of the epidote family. When zoisite synthesis is attempted at low pressures and temperatures from a mix of appropriate composition, phases on the right of the above equation tend to be formed, or if leaching of silica occurs hydrogarnets may form. In the present experiments two starting materials were used; an iron-poor clinozoisite and an epidote which, judging from refractive index, contained around 13 per cent iron sesquioxide (Fe_2O_3). These phases were first thermally decomposed to form the high-temperature assemblages and then mixtures of the epidote mineral and high-temperature products (that is, all the phases in the above equation) were sealed in small capsules with water and allowed to react for 30–80 days at 2,000 bars pressure and then examined by X-rays and microscope. With a mixture of epidote and decomposed epidote, it was found that epidote formed strongly at 505° and 630° C. while at 715° C. anorthite, garnet and magnetite were the dominant products. A mixture of clinozoisite and decomposed clinozoisite produced clinozoisite at 605° C. and anorthite and garnet (from refractive index and X-ray measurement close to grossularite) at 740° C. At 605° a few grains of garnet could be recognized, but growth of clinozoisite was spectacular. In two runs with epidote composition excess quartz was added and at 465° and 605° C. strong growth of epidote occurred.

These results indicate clearly that, relative to the normal products of synthesis, the epidote minerals are stable at moderate temperatures and water pressures. Thermodynamic consideration of entropy and changes in volume involved indicates that little pressure would be needed for their formation at low temperatures from suitable compositions. At temperatures around 300° C. and below, present results[4] indicate that zeolites will become stable. Work on other reactions involving calcium aluminosilicates in progress also demonstrates that this method of mixtures may be of value in proving relative stability of phases whenever it is suspected that the slow step in the reaction kinetics is nucleation.

This work has been supported by grants from Research Corporation and the Petroleum Research Fund, American Chemical Society.

Relic-Soil on Limestone in South Wales

THE Worm's Head, part of the Nature Conservancy Gower Coast National Nature Reserve, lies at the south-western tip of the Gower Peninsula of Glamorganshire, South Wales. It is a Carboniferous limestone headland accessible only at low tide across a wave-cut limestone platform. On the southern side of the Inner Head (Ord. Surv. Grid Ref. *SS* 395873) is a section in Pleistocene deposits of a type recorded widely in Gower[1–3], and elsewhere in southern Britain. This can be summarized from the base upwards as follows: (1) Wave-cut limestone platform; (2) raised beach of calcite-cemented limestone pebbles banked against solid limestone; the *Patella* beach; (3) remnants of bright red sandy clay loam, 10–18 in. thick, containing rare limestone pebbles with red weathered outer zones; (4) brown loam containing abundant angular limestone, a periglacial head deposit. The thickness of this is variable from 0 to 10 ft.; (5) dull grey-brown stony sandy loam, glacial drift containing abundant Old Red Sandstone and Carboniferous grits and sandstones; where this is preserved on the flanks of the Worm's Head, the depth averages 4–6 ft.; (6) dull, grey-brown, sandy loam, almost stoneless, similar to the matrix of horizon 5, resting variously on horizons 2, 3 or 6.

The *Patella* beach (Horizon 2) includes fauna characteristic of a cold climate, and deposits overlying this beach elsewhere in Gower have been found to have included a fauna indicating "a climate more genial than that of the present day"[3]. Horizon 3 is interpreted here as relics of a soil which had developed on Carboniferous Limestone prior to the return of periglacial and glacial conditions responsible for Horizons 4–6.

The colour of Horizon 3 is red (Munsell colour $2.5YR4/6\text{-}5/8$). It is sticky and mouldable when wet, moderately massive when dry. Field texture, silty loam to silty clay loam, is heavier than that given by laboratory analysis. This, by the hydrometer method, is sandy clay loam (5·5 per cent American silt, 28 per cent clay). Organic carbon content is 4 per cent and free iron oxides (by Deb's method) 3 per cent. The clay fraction minerals are dominantly illite with a minor proportion of chlorite. Thin sections reveal a skeleton of clean sub-angular quartz of mainly fine sand size in a matrix of yellow-brown colour. There are rare, small, round concretionary flecks of calcite and roughly rounded dark red-brown segregation patches of iron oxides, the latter translucent with included quartz grains. Small, round or ovoid black opaque areas, reddish-brown in reflected light, are apparently also iron oxides. Between crossed polars the clay is markedly birefringent. There are moderately well and strongly oriented coatings around sand-grains and the general clay areas are seen as fine aggregates, in the terminology of Brewer and Haldane[4]. The fabric seen in sections of this material is similar to that described in rotlehm from Cyprus[5] and in material discussed by Dalrymple[6], notably a red clay from head deposit at Slindon, Sussex. Examination of slides, including the Dalrymple material, at the Institute of Archæology, University of London (by permission of Dr. I. Cornwall), showed comparable fabric also in rotlehm from Morocco. The oriented clay is not concentrated in channels or pores, but is uniformly distributed as coatings to grains throughout the sections examined. The orientation apparently results from alternate wetting and drying of the soil-clay *in situ* rather than from illuviation of mobile clay[7]. This fabric is closely comparable to that described for terra fusca[8], a soil of braunlehm type occurring on limestone in climates of humid conditions, slightly warmer than most of Britain. The occurrence of iron segregations and of small concretions is considered a stage in the process of rubefaction[9] leading in hotter climates to a development of terra rossa from terra fusca, and rotlehm from braunlehm.

The interpretation of this material, in field morphology close to siallitic terra rossa and in micromorphology close to terra fusca, is that it is a soil of transitional character between these two sub-types. The climate for its production is likely to have been essentially similar to that of south-western Britain to-day, but with warmer summers. The shallow soils developed on limestone on the mainland cliffs adjacent to the Worm's Head show in thin section weakly developed moderately oriented coatings to sand grains, but have a higher organic matter content and well-developed crumb or granular structure. It seems that only the first stages of transition from brown earth to terra fusca have been produced as a result of post-glacial conditions in this area. A detailed study of a range of soils on limestone in Glamorgan is likely to be interesting. In particular, it is of geological and pedological significance whether the red silty clay frequently preserved over limestone in the Vale of Glamorgan and Gower is a relict material or a result of post-glacial weathering. It is suggested that it may well prove to be an interglacial relic occurring locally south of the deposits of the last glaciation.

I am grateful to Dr. D. A. Osmond for helpful discussion on this topic.

CRYSTALLOGRAPHY

Crystal Growth in Paraffin

AN increased interest in crystallization phenomena, especially in polymeric materials, is shown by the number of publications devoted to the subject[1]. I originally published observations of crystal growth of a dislocation mechanism in polymeric material[2]; however, some observations remained unpublished and increased interest in this general area prompts this communication.

In an attempt to study growth mechanisms in polymeric material by starting with paraffin and building up to longer-chain polymers, some thought was given to how the dislocation promoting the growth is introduced. Frank[3] proposed that this dislocation is introduced into the nucleus as a result of a buckling mechanism. It was thought that this process may be checked by purposely introducing impurities to cause strain that may aid the buckling process.

Pure paraffins (hexatricontane and pentatricontane) were crystallized from solutions of petroleum ether on electron microscope grids. The resulting crystals grown were regular lozenge-shaped with dislocation spirals very clearly evident (Fig. 1). These crystals are familiar and have been previously reported by other workers[4] and are used as a standard. Into the same solutions from which these standard crystals have been grown, small amounts of 'impurity' material are added, and the new crystals grown are

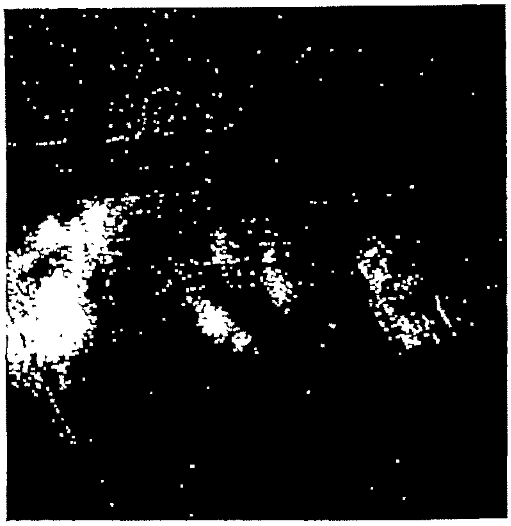

Fig. 1

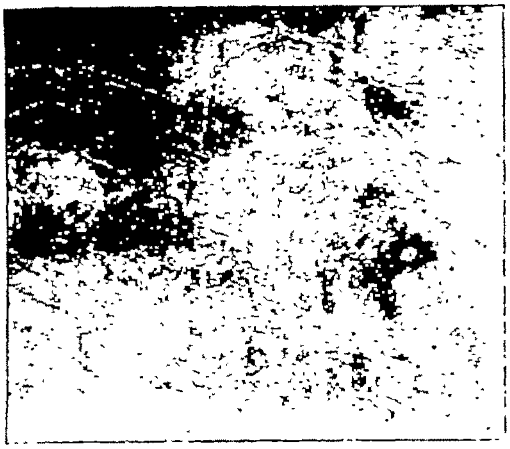

Fig. 2

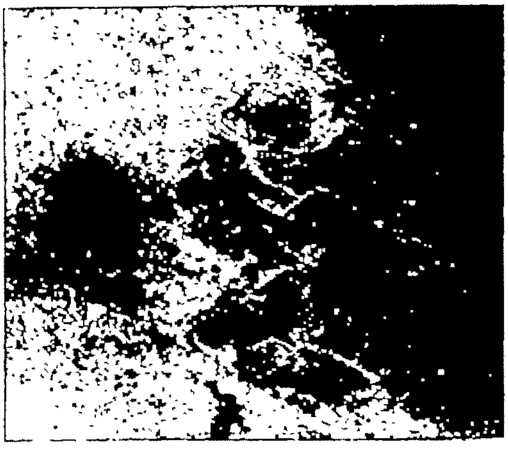

Fig. 3

examined. Impurities in the form of material with small particle sizes (dyes and colloids) were tried. None of these was successful in introducing any changes in the resulting crystals. However, small amounts of hexatricontane, either solid or from solution, when added to pentatricontane solution, and vice versa, altered the growth mechanism. The resulting crystals were changed in morphology and had many more dislocation spirals evident per growth area. (A typical example is shown in Fig. 2.) It is felt that the impurity paraffin may aid in formation of dislocations as a result of its misfit with the host paraffin.

A phenomenon of similar type may be occurring in polymeric material. Fig. 3 shows crystals grown from solution of 'Marlex No. 20' (linear polymethylene) from xylene.

Five Co-ordinated Titanium in $K_2Ti_2O_5$

It is widely believed that oxygen atoms may be extracted at random from the lattices of metallic oxides, and X-ray powder photographs have suggested that little or no modification of the structure of the original stoichiometric substance occurs. In particular, evidence has been adduced that the perovskite lattice can persist between the limits ABO_3—$ABO_{2.5}$, provided that the six co-ordinated ion B is one of the metals, titanium, vanadium, cobalt or iron[1]. In order to evaluate this proposal, we are examining the crystal structures of ordered, oxygen-deficient compounds in which the ionic radii comply with the rules enunciated by Goldschmidt[2] for the perovskite structure. $K_2Ti_2O_5$ was recently reported by Schmitz-Dumont and Reckhard[3] to have a large unit cell of low symmetry, and this could, perhaps, be due to the regular omission of some of the oxygens from a perovskite lattice. We now wish to report briefly that a complete X-ray structure determination does not support this view.

Crystals of $K_2Ti_2O_5$ which are formed by slowly cooling a melt of potassium carbonate and titanium dioxide in the molar proportions 1 : 2 decompose rapidly in moist air, and require protection during X-ray exposures. They crystallize as monoclinic needles with the unit cell dimensions $a = 11{\cdot}374$, $b = 3{\cdot}799$, $c = 6{\cdot}616$ Å., $\beta = 100{\cdot}10°$, and the structure which was derived unambiguously from Patterson and Fourier projections satisfies the space-group $C2/m$. The titanium atoms are each co-ordinated to five oxygens grouped as a slightly distorted trigonal bipyramid. Two of these have an edge in common (Fig. 1), and this double unit forms an endless string elongated along y. Strings are joined to one another by having corners (oxygen atoms) in common, and this results in the formation of a two-dimensional sheet or layer of composition $(Ti_2O_5)^{2-}$. The layers are held together by the potassium atoms (Fig. 2), which have a curious unsymmetrical environment of eight oxygens, bearing only a superficial resemblance to the cubic site of the perovskite structure.

Instead of creating vacancies, the loss of some of the oxygen atoms has caused the remainder to regroup into a configuration around the titanium

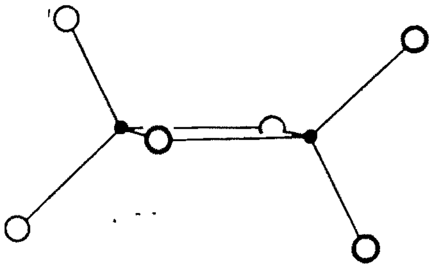

Fig. 1. Double trigonal–bipyramidal groups of oxygen (large circles) around titanium (small circles), seen in projection

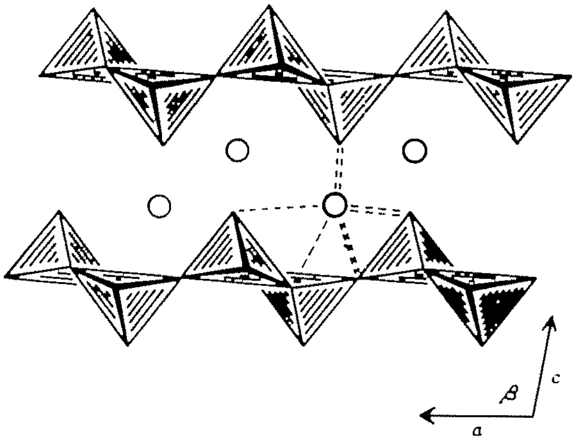

Fig. 2. Projection of the structure of $K_2Ti_2O_5$ on to (010), drawn as linked polyhedra. The potassium atoms are shown as circles, and the bonds to the nearest oxygens are drawn as broken lines for one of them

atom that is so unusual for this element that it has never, to our knowledge, been reported before. The structure of $K_2Ti_2O_5$, as a whole, has certain similarities to that of V_2O_5 in which, as in $KVO_3.H_2O$, the vanadium has five-fold co-ordination of a similar kind[4]. In the magnetoplumbite structures some of the Fe^{3+} ions also have the trigonal bipyramidal co-ordination[5]. Oxygen deficiencies in perovskites containing one or other of these cations might therefore be expected to cause, at the very least, a local rearrangement of oxygens from octahedral to trigonal bipyramidal and in this sense the term 'anion vacancy' has little real significance.

CHEMISTRY

Ultra-violet Absorption Spectra of the Diazines

No rotational analysis of an electronic transition has been reported for a molecule containing as many as ten atoms. However, preliminary spectrograms of pyrazine (Fig. 1) showed fine structure clearly susceptible to analysis (Fig. 2). Twelve bands which were relatively free from overlapping were photographed in the fourth order of a 150,000-line grating, and the rotational constants and accurate band centres were obtained. Similar treatment was possible for the 3200 Å. absorption of pyrimidine and the 3700 Å. absorption by pyridazine. The constants obtained for the respective 0–0 bands are:

	ν_0	$\bar{B}_0'' = \frac{A_0'' + B_0''}{2}$	$\bar{B}_0' = \frac{A_0' + B_0'}{2}$
Pyrazine	30,875·80 cm.$^{-1}$	0·2048 cm.$^{-1}$	0·2036 cm.$^{-1}$
Pyrimidine	31,072·5$_6$	0·205$_3$	0·204$_7$
Pyridazine	26,648·75	0·2034	0·2030

Resolved perpendicular structure of a hybrid band of pyridazine (Fig. 3) gives, from the average spacing of the P_Q branches, a very rough value for the inertial constant $(C' - \bar{B}') \simeq (C_0'' - \bar{B}_0'')$, namely, $0·10_5$ cm.$^{-1}$. However, for each molecule, the lack of other precise data prevents determination of the geometrical structures. Parameters which give agreement with the observed $\bar{B}_0''$-value of pyrazine are shown in Fig. 1.

Since each 0–0 band is clearly of the parallel type, the electronic transition moment must in each case be parallel to the axis of largest inertia and perpendicular to the plane of the molecule.

Partial vibrational analyses have been given for the systems of pyrazine[1,2] and pyrimidine[3], but evidently not for that of pyridazine. Precise measurements of about 800 sharp Q branch edges of pyridazine, as well as of fine structures of eleven bands, have therefore been made, between 25,675 cm.$^{-1}$ and 28,775 cm.$^{-1}$. It has been possible to arrange the

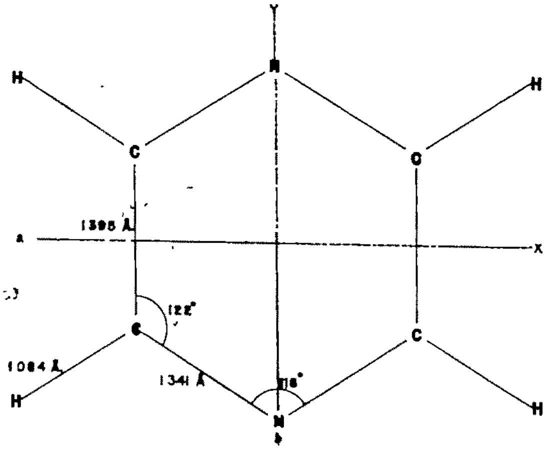

Fig. 1. Planar pyrazine (1,4 diazine). A nearly oblate symmetric top of point group D_{2h}. Note the choice of axes. Compare the point group C_{2v} for pyrimidine (1,3 diazine) and pyridazine, for each of which z is the two-fold axis and x is perpendicular to the molecular plane

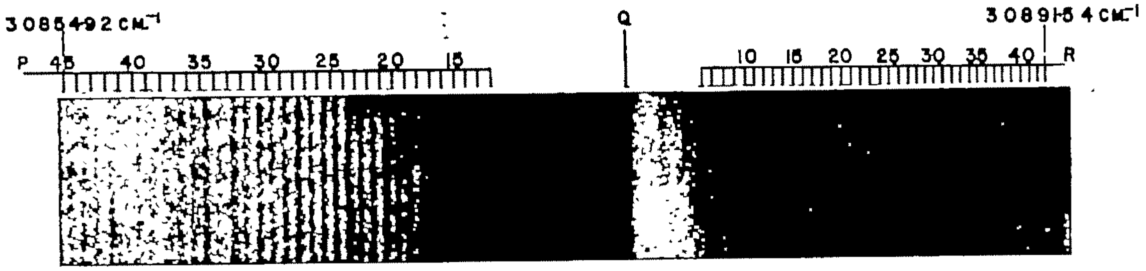

Fig. 1. 0–0 band of the 3200 system of pyrazine. Parallel structure typical for all three molecules. The Q-branch edge corresponds very closely to the band centre and is sharpest for pyridazine

bands into a single band system about the origin given above. Particularly sensitive checks of the vibrational analysis were found in 'hot' bands originating in the levels 664·80 cm.$^{-1}$ (ν''_{6a}) and 969·83 cm.$^{-1}$ (ν''_1). Each of these values agrees well with the infra-red and Raman spectra of pyridazine[4] and each is observed several times in the present spectrum. Almost all the bands are degraded slightly toward longer wave-lengths, but a weaker system of blue-degraded bands was found to originate at 27,182·8$_4$ cm.$^{-1}$ (Fig. 3) and could be included in the stronger system if it was assumed that the 534·0$_5$ cm.$^{-1}$ separation from the 0–0 band represents ν'_{6b}, a ring-stretching frequency of symmetry B_1. The assignment was confirmed by observation of the (0–1) and (1–1) bands of the same vibration and by observation of the perpendicular structure of Fig. 3. The most striking feature of the vibrational analysis is the decrease of ν_{6a} from 664·80 to 372·71 cm.$^{-1}$, but two other ground-state frequencies, ν''_{9a} = 1,153·1$_5$ cm.$^{-1}$ and ν''_{12} = 1,068·60 cm.$^{-1}$, and numerous excited-state frequencies of less-certain assignment, were also obtained. No out-of-plane vibrations are important in the spectrum, so it is concluded that the pyridazine molecule is planar in the excited electronic state, B_1.

The previous work on the vibrational assignments for pyrazine and pyrimidine has indicated that it will require more than one electronic transition per molecule to account for the observed bands. Since this was not necessary for pyridazine, it has seemed worth while to review the list of pyrazine bands given by Hirt[2] and the list of pyrimidine bands given by Uber[3]. Where available, the more accurate head measurements and band centres of the present work have been used. All the bands of pyrazine between 29,965 cm.$^{-1}$ and 32,053 cm.$^{-1}$, except the weakest, and all the main progressions of the pyrimidine spectrum, have been considered. Consistency with exact vibronic selection rules and with the infra-red and Raman spectra of the two molecules[4] has been imposed. A few re-assignments of the Raman spectra have been necessary. All the bands considered may be accounted for by the following fundamental vibrational frequencies and combinations of them about the respective 0–0 bands given above. For pyrazine: ν'_{6a} (A_g) = 582·61, ν''_4 (B_{2g}) = 257, ν'_4 = 477, ν''_5 (B_{2g}) = 596·06, ν'_5 = 414, ν''_{9a} (A_g) = 1,229, and ν'_{9a} = 1,108 cm.$^{-1}$. For pyrimidine: ν''_{6a} (A_1) = 679, ν'_{6a} = 530, ν''_{16a} (A_2) = 344, ν''_{12} (A_1) = 1,071, ν'_{12} = 1,015, ν''_1 (A_1) = 1,003, and ν'_1 = 1,291 cm.$^{-1}$. The reason for the prominence of non-planar vibrations, B_{2g} and A_2, in the spectra is indicated by the Franck–Condon principle: pyrazine and pyrimidine molecules are evidently slightly non-planar ('chair-form') in the excited electronic states, B_{1u} and B_1, respectively.

If the pyridazine molecule is planar in the excited state, while the related molecules are not, one may expect lower energies for excited pyridazine molecules than for excited pyrazine or pyrimidine molecules. The 4,300 cm.$^{-1}$ shift to lower energies of the pyridazine spectrum is thus readily understood. These tentative conclusions about configurations are being tested by accurate measurements of the band-heads of pyrazine and pyrimidine, by work on the dependence on temperature of each spectrum, and by examination of certain of the isotopically substituted compounds. A complete report of all this work will be published elsewhere.

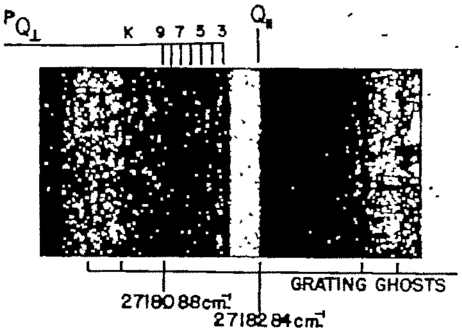

Fig. 3. Structure near the band centre of the hybrid band at 27,182·8$_4$ cm.$^{-1}$. Leading lines identify the Q-branch of the parallel component and several of the ^PQ-branches of the perpendicular component. On account of the slight asymmetry of the molecule, $^PQ_1$ and $^PQ_3$ are not observed as collected, line-like features

This investigation was supported in part by a grant from the Petroleum Research Fund administered by the American Chemical Society, for which we are grateful. Initial Stages of Oxidation of Coal

OUR knowledge on the initial stages of oxidation of coal in air or oxygen is far from complete, though it is long known that the first stage is the formation of coal–oxygen complex and peroxygen-like bodies[1]. It is this stage and onwards where information on the mechanism of the progress of oxidation is scant. We have recently found that in the first phase of coal oxidation dehydrogenation appears to be the main reaction, without any drastic destruction of the carbon structure of coal.

Earlier[2,3] it was shown that prolonged oxidation of coal at temperatures ranging from 170° C. to 220° C. leads to preferential oxidation of the non-aromatic part leaving the aromatic nucleus unaffected, and therefrom structural parameters of coal were deduced[4-7]. The same mode of oxidation at 170° C. in air has been adopted to follow up the initial chemical changes in case of high-rank vitrain. Samples of oxidized coal were drawn at small intervals of time at the initial stages. The material balance, ultimate analysis and functional group analysis, including methyl group estimation, were done for all these oxidized samples, and the results are given in Table 1. The input and output of carbon and hydrogen before and after oxidation at different stages are also shown.

The elemental balance indicates that dehydrogenation is the main reaction at the initial stages, the loss of carbon being comparatively small.

The nature of this dehydrogenation has been studied by treating the oxidized samples with sulphur[8]. It will be seen (Table 2) that the amenability to further dehydrogenation with sulphur[8] (Vesterberg's) progressively decreases with oxidation.

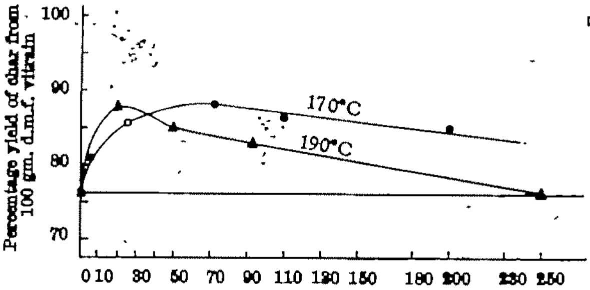

Fig. 1. Effect of oxidation on yield of char

The parallelism between the action of sulphur[8] and oxygen/air appears to be extended by the carbonization behaviour of such treated samples, for example, under both types of treatment: (1) caking property is undermined; (2) the yield of tar is inhibited; (3) the char yield increases, apparently, at the expense of the tar-forming structures. The yield of char progressively increases with the extent of oxidation and at the 72-hr. oxidation stage the yield of 'extra' char was found to be almost the same as is obtainable[8] from carbonization of the vitrain in presence of sulphur (Table 2). It has also been found that if the oxidation is continued beyond this stage, the yield of extra char decreases (Table 2), so much so, that after a time a stage is reached where the original yield of char is restored (Fig. 1).

Table 1. ELEMENTARY COMPOSITION AND ITS BALANCE AT DIFFERENT PERIODS OF OXIDATION
(Calculations based on 100-gm. unit coal basis)

(ii) 250 hr.	—	76·4 (char)	nil	0·2

* Sulphur-free yield.

Though the effect of dehydrogenation caused either by air/oxygen or sulphur on the carbonization behaviour is almost the same, yet the overall reaction with sulphur and oxygen does not appear to be a complete parallel. Practically no loss of carbon occurs during sulphur dehydrogenation[8], whereas 4–5 per cent of the carbon of coal is lost during air dehydrogenation. How and whence this loss occurs during the initial stages of oxidation is not readily explicable at the moment; but the fact that the tar-forming part of carbon structure can be completely stabilized at a certain stage of coal oxidation (Table 2) would possibly indicate that the loss at this stage must not have resulted at least from the destruction of tar-forming bodies.

The above phenomenon of air dehydrogenation and its consequent effects on the carbonization behaviour have also been observed to be true at other temperatures of oxidation as well. The only difference is that the higher the temperature, the shorter is the period required to cause the above chemical changes. The rate of this oxidative dehydrogenation reaction has also been found to be approximately doubled for each 10° C. rise in temperature (Table 1).

The inhibition of the tar formation on oxidation of coal has been common knowledge for a long time, but the causes of its inhibition at the initial stages of oxidation now have become evident from our work. The decrease or the complete inhibition of the formation of tar is not due to the destruction of tar-forming bodies, but apparently to their reorganization. Further, these findings on the initial stages of oxidation, *vis-à-vis* the action of sulphur[8] on coal, obviously raise some pertinent questions relating to the peripheral structure of coal which will be dealt with elsewhere.

Simultaneous Measurement of Adsorption and Electrodekinetic Parameters at Metal Surfaces

A RECENT communication by Blomgren and Bockris[1] described a radiochemical technique for the measurement of adsorption on metal surfaces, the metal being deposited on the mica window of a gas proportional counter. The metallized window serves as an electrode at which adsorption and the usual electrodekinetic parameters may be measured simultaneously. An obvious disadvantage of the above method, the introduction of a counter into an electrolytic cell, has been avoided by a technique developed in this Laboratory for the study of the poisoning by antimony of the hydrogen evolution reaction on nickel. The method employs radioactive adsorbates in conjunction with the 'transparent-cathode' technique of Joliot[2]. The latter required modification in detail but not in principle.

The technical problem was to find a simple method of placing a thin metal window on a glass vessel in such a way as to obtain a water-tight seal without introducing any source of impurity into the cell. It was found that the desired result could be obtained by holding annealed gold foil against a heavy, polished lip of a circular aperture by mechanical means only. A cross-section through such an aperture in the base of a spherical 'Pyrex' flask is shown in Fig. 1a. The foil (nickel-plated in this case) is held in a nickel 'holder' (hatched region) in which it had previously been annealed. The holder is shown in plan in Fig. 1b, the cross-section shown in (a) being taken through the dotted line. The upper and lower parts of the brass clamp, Fig. 1a, are held together by four bolts threaded into the upper, horse-shoe shaped, part. The foil is placed directly against the polished glass lip and the mechanical pressure is transmitted through a rubber washer and a rubber ring, shown in solid black cross-section. The foil used in the present work was 1/100 mm. thick and supported readily 50 cm. of water on an unsupported area of 2 cm.^{2}. Thinner foil could undoubtedly be used, if it can be found free from pin-holes.

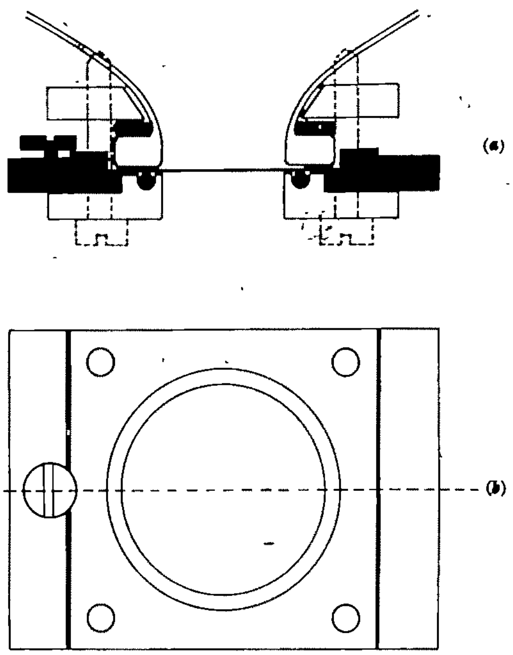

Fig. 1. *a*, Gold-foil window clamped in position; *b*, nickel holder for annealing foil

The above device permits simultaneous measurement of over-potential and amount of radiopoison adsorbed on the electrode. Some typical results are shown in Fig 2, for the poisoning by antimony of cathodic hydrogen evolution on electrodeposited nickel in 0·1 *N* sulphuric acid solution. The solution had been purified by pre-electrolysis before coming into contact with the nickel-plated foil. Fig. 2 shows the increase in cathodic overpotential for a given current (5×10^{-4} amp.cm.$^{-2}$) as a function of the amount of antimony (marked with antimony-124) adsorbed on the cathode. It was shown experimentally that the background due to antimony-124

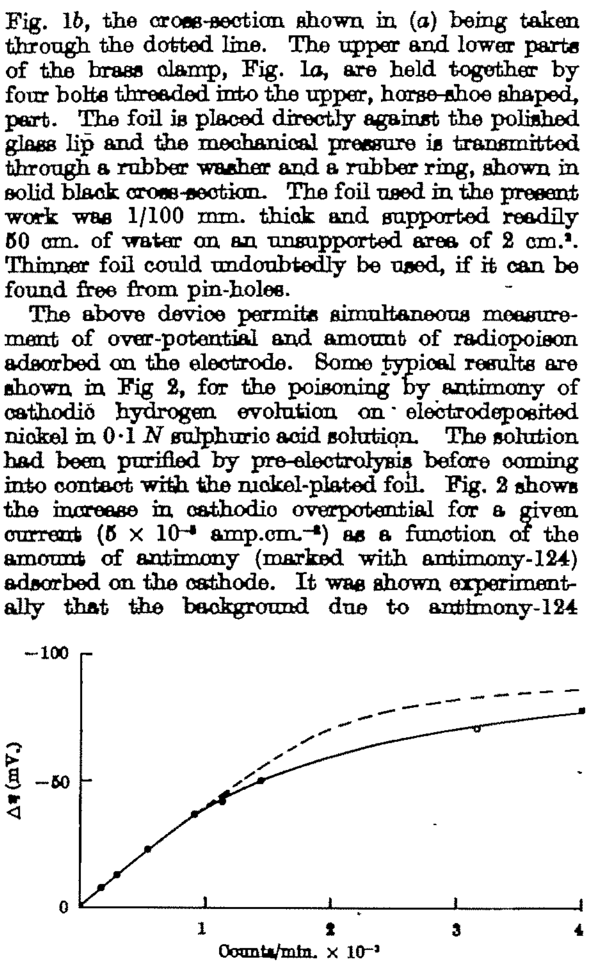

Fig. 2. Variation of over-voltage with amount of antimony adsorbed; - - -, theoretical; ——, experimental

dispersed in solution (400 ml.) was negligible. The theoretical curve, Fig. 2, was made to coincide with the initial part of the experimental curve by assuming that one atom of antimony deposited on a pure nickel surface alters the hydrogen-evolution characteristics of $2 \cdot 6\gamma$ surface nickel atoms, where $\gamma > 1$ is the surface roughness factor. Experimental details and theory will be given elsewhere.

A. M. PEERS

Laboratoire Curie,
Institut du Radium,
11 Rue Pierre-Curie, Paris, 5.

[1] Blomgren, E. A., and Bockris, J. O'M., *Nature*, 186, 305 (1960).

[2] Joliot, F., *J. Chim. Phys.*, 27, 119 (1930).

MR. PEERS presents a solution to the technical problem of mounting a metal film in contact with a solution in such a way that cements, etc., do not cause contamination of the solution. Mr. Peers's solution of this problem is not compatible with the gradual approach of solution to the metal surface which is a characteristic feature of the method described by us. This method of gradual approach is necessary when the solution background exceeds a small fraction of the radiation from the adsorbed amount (Fig. 1 in our communication). However, Mr. Peers points out that the background from his solution was negligible compared with the activity of the adsorbed amount. Simple computation indicates that the maximum concentration of adsorbable species in the solution has to be smaller than about 10^{-6} mole $l.^{-1}$ in Mr. Peers's method. Our technique enables determinations of adsorbed amounts (with a precision of 0·1 of a monolayer) up to concentrations of adsorbate in the solution of about 10^{-3} mole $l.^{-1}$.

It may be mentioned that the problem of bringing the metal film in contact with the solution without causing contamination to the solution has also been solved by us, though in a different way from that now described by Mr. Peers. One method used by us consists in mounting the metal foil flush on a holder in such a way that the foil covers the edges and sides of the holder. Another technique consists of evaporating a metal film on a mica foil fused to the edges of a glass cylinder which surrounds the counter, using a low-melting glass. These details were excluded from our brief communication. A full account of the results will be published elsewhere.

Structure of the Trinuclear Basic Acetates

THE trivalent metal ions, for example, Cr^{3+}, Fe^{3+} and Al^{3+} form a variety of basic acetates which are usually supposed to contain complex ions of the type $[M_3(Ac)_6(OH)_2]^+$ (refs. 1 and 2). In addition, a very few compounds containing only one hydroxyl group have been described[3]. The whole group of compounds is of considerable interest in view of their unusual magnetic properties[3,4].

The following are among the most significant findings of the many studies which have been reported. (1) The great majority of compounds contain six or more acetate groups for each group of three metal ions. (2) Trinuclear complexes are formed only if the complex ion can be formulated to contain either hydroxyl groups or water molecules, that is, one cannot replace 'hydroxyl' groups by halide ions. (3) Strong magnetic interactions occur between the metal ions[3,4].

Here I wish to propose a structure for the group of compounds based on the experimental evidence. First, we suppose that each metal ion is octahedrally co-ordinated by negative ions or polar molecules, for this is the only type of co-ordination known for the Cr^{3+} ion. This excludes structures related to that of the cupric acetate dimer involving direct metal–metal bonds. Next, we remember that magnetic interactions between metal atoms joined by one or two hydroxyl groups, for example, between Cr^{3+} ions, are usually weak while interactions via oxide ions are often strong[5]. Finally, we note that acetate groups often link pairs of metal atoms, as in basic beryllium and zinc acetates[6].

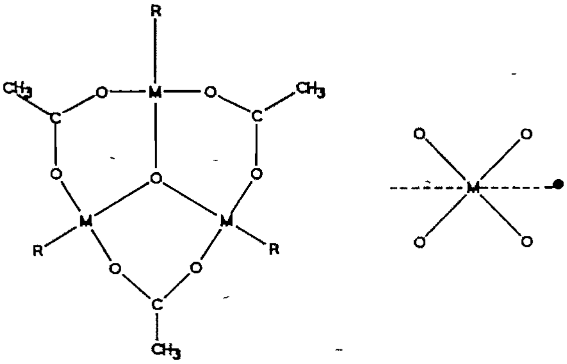

Fig. 1. Proposed structure for the $[M_3(Ac)_6O]^+$ ion: *a*, projected on to the M_3O plane; *b*, seen along an M—O direction, the dotted line indicating the M_3O plane

These considerations suggest that the structure basic to the whole group of compounds may be represented as in Fig. 1. The three metal atoms are arranged in an equilateral triangle about a central O^{--} ion. The positions *trans* to the O^{--} ion may be occupied by any of the ligands normally associating with trivalent transition-metal ions, for example, water, amines, further acetate groups and halide ions. By varying these groups a variety of different complexes can be obtained. The six acetate groups complete the octahedral co-ordination about the metal ions, each one lying completely to one side of the plane of the metal ions and linking a pair of them. A simple geometrical construction shows that this structure builds very nicely if the usual bond-lengths are assumed.

The proposed structure is closely related to that of basic beryllium acetate. It differs in that the central O^{--} ion is trigonally rather than tetrahedrally co-ordinated. (Trigonally co-ordinated O^{--} ions occur in the rutile type oxides TiO_2 (ref. 6), etc.) The apparent requirement for at least one hydroxyl group in the complex is explained if it is assumed that it is really an O^{--} ion which is involved; if OH^- were really present as such it is difficult to see why it should not be replaced, for example, by halide ions.

While other structures are possible, for example, the metal ions might lie at the vertices of an equilateral triangle with two hydroxyl groups, one above and one below the centroid of the triangle, none builds so neatly.

Positions of Thorium and Uranium in the Periodic Table

Element 90 of the Periodic Table, thorium, ordinarily appears as the first element of the actinide series, appended below cerium at the bottom of Table 1. This construction gives the impression that thorium is the second member of a series starting with actinium in the scandium group, just as cerium is the second member of a series starting with lanthanum in the scandium group. From the point of view of alloying behaviour it is inconsistent to consider thorium as related to the scandium group. During the course of a continuing investigation into the alloying behaviour of scandium and titanium group elements with the platinum metals, it was noted that thorium behaves as if it were a member of the titanium group. Evidence is given in Table 1 in which the crystal structure of an intermetallic compound of composition AB_3 is identified in the usual manner by the prototype of the compound family. Crystal structure data pertaining to certain of these compounds have been published[1], and for the remainder will be published shortly.

Table 1. Crystal Structures of AB_3 Intermetallic Compounds

B element	Group IV *A* element				
	Ti	Zr	Hf	Th	U
Rh	Cu_3Au	Cu_3Au	Cu_3Au	Cu_3Au	Cu_3Au
Ir	Cu_3Au	Cu_3Au	Cu_3Au	—*	Cu_3Au
Pd	$TiNi_3$	$TiNi_3$	$TiNi_3$	$TiNi_3$	$TiNi_3$
Pt	Cu_3Au	$TiNi_3$	$TiNi_3$	$ThPt_3$	$MgCd_3$

B element	Group III *A* element				
	Sc	Y	La	Ho	Ac
Rh	Cu_3Au	—*	—*	—*	?
Ir	?	—*	—*	—*	?
Pd	Cu_3Au	Cu_3Au	Cu_3Au	Cu_3Au	?
Pt	Cu_3Au	Cu_3Au	—*	Cu_3Au	?

* No compound of AB_3 composition exists; in its place are two phases, one of which is a Laves phase, AB_2.

It is instructive to consider the series of AB_3 compounds in which the *B* element is palladium. Those compounds in which the *A* element is titanium, zirconium, hafnium, thorium or uranium all have the $TiNi_3$-type structure, but those in which the *A* element is scandium, yttrium, lanthanum or holmium have the Cu_3Au-type structure. Likewise, the elements titanium to uranium form a compound having the Cu_3Au-type structure when *B* is rhodium, but the *A* elements yttrium, lanthanum and holmium do not form any AB_3 compound with rhodium.

The recognition of the resemblance of thorium to titanium, zirconium and hafnium is not new. In fact, an older version[2] of the Periodic Table placed thorium, palladium and uranium in the titanium, vanadium and chromium groups, respectively. The evidence for such a construction was largely the crystal structure resemblance among the heavy elements.

A recent review by Makarov[3] discusses the similarity between the 5*f* elements (thorium and those following it) and elements of the titanium, vanadium and chromium groups. A major point made by Makarov is that the 5*f* elements exhibit a well-established resemblance to the titanium, vanadium and chromium group elements, but that this resemblance has been obscured by the more recent concept that the transactinium elements are characterized by the presence of electrons in the 5*f* shell. Makarov points out that the most convincing evidence for the similarity between thorium and uranium, and the titanium, vanadium and chromium group elements is the formation of continuous or extensive series of isomorphous solid solutions of β-thorium and γ-uranium with the body-centred cubic forms of titanium, zirconium, hafnium, niobium and molybdenum. It seems to me that this argument actually indicates a closer resemblance between uranium and zirconium than between uranium and molybdenum, because the extent of solid solubility is much greater in the uranium–zirconium system than in the uranium–molybdenum system. Furthermore, my newly reported results and other recent data mentioned below do not support the earlier point of view that uranium resembles the chromium group elements. I have found a compound URh_3 of Cu_3Au-type, but it has been shown[4] that there is no $MoRh_3$ compound of the Cu_3Au-type. Previous work[5] had established a compound UPd_3 of the $TiNi_3$-type, but no $MoPd_3$ (ref. 6) compound was reported.

In summary, the data on AB_3 compounds discussed above indicate that both thorium and uranium resemble the titanium group elements, and furthermore that uranium bears little resemblance to molybdenum of the chromium group. It is considered that the concept in which both thorium and uranium are members of the titanium group is not inconsistent with the 'thoride' hypothesis advanced by Zachariasen[7], according to which thorium, not actinium, is the parent element of the heavy-metal series.

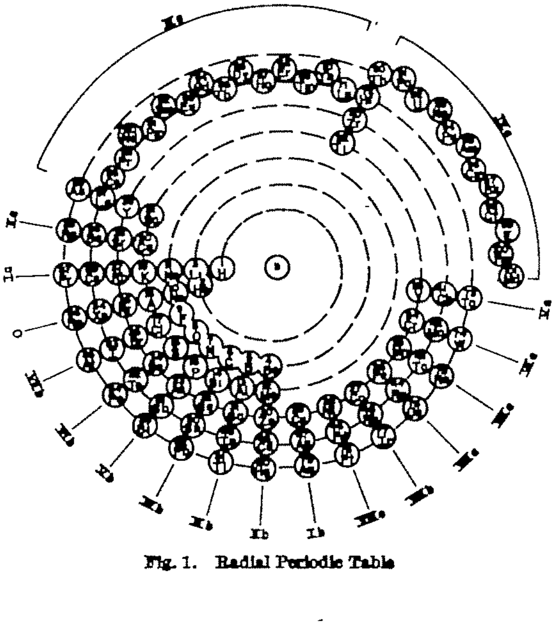

Fig. 1. Radial Periodic Table

It is thought that a Periodic Table which is realistic from the point of view of transition alloy behaviour should show thorium in a dual role, first as a member of the titanium group and secondly, as the parent of a thoride series. A possible form of such a diagram is shown in Fig. 1. There are two major advantages to this radial form of the Table. First, the lanthanide and thoride series are shown in their proper groups, rather than appended. Secondly, no implication is made that the thorides are a 'heavy rare earth' series. (It is recognized that evidence exists for considering the elements from americium on as related to the lanthinides.) An admitted disadvantage of the radial form is the dissimilarity to the familiar and useful rectangular table.

This work was performed under the auspices of the U.S. Atomic Energy Commission.

BIOCHEMISTRY

Phosphoproteins and Mitochondrial and Cell Water

IN previous communications[1,2] it was shown that several antihistamine drugs in concentrations which do not affect respiration or phosphorylation reduce the rate of swelling of isolated mitochondria and also diminish the rate of extrusion of water by these particles. It was found that the drugs greatly reduce the rate of turnover of phosphoprotein phosphorus in such systems.[2] This work has now been extended, and it has been found that a variety of agents which affect mitochondrial swelling and 'contraction' also affect the phosphorylation of proteins. A similar relation appears in liver slices taking up and extruding water under appropriate conditions. Amytal and azide inhibit mitochondrial 'contraction'[3], whereas 2,4-dinitrophenol does not. Phosphoprotein–phosphorus falls to low levels during swelling, and compounds which prevent this change preserve the phosphoproteins; this, however, might be a secondary phenomenon. During 'contraction' there is phosphorylation of protein; this is shown in Table 1, which also shows the effects of amytal, azide, 2,4-dinitrophenol and 'Phenergan', a phenothiazine antihistamine drug. It will be seen that there is a correlation between the increase in optical density of the mitochondrial suspension and the phosphorylation of protein. If the time-course of 'contraction' is followed, there is a close correlation between these two processes. Furthermore, if the mitochondria are allowed to re-swell, this event is preceded by a fall in phosphoprotein-level, even in the presence of excess adenosine triphosphate.

If liver slices are incubated anaerobically at 38° for 30 min., they take up water, which is extruded on admission of oxygen. 'Phenergan', which is known to protect liver slices from certain types of injury[3,4], inhibits this extrusion of water in much the same manner as it reduces mitochondrial 'contraction'. In Table 2 is shown an experiment with such a system. It can be seen that a diminution of extrusion of water by the drug is accompanied by failure to phosphorylate protein, though adenosine triphosphate-levels are the same as in the control. This relationship has been observed under other conditions in which extrusion of water is prevented (for example, after prolonged anoxia) even though adenosine triphosphate synthesis occurs normally. If phosphorus-32 is present in the medium, the phosphoprotein–phosphorus turns over rapidly, the specific activity of the newly formed phosphoprotein approaching that of the newly formed adenosine triphosphate within 60 min. 'Phenergan' greatly reduces the rate of turnover, but these experiments are complicated by the compartmentalization of inorganic phosphate and adenosine triphosphate within the cell. It should be noted that, under certain conditions, the antihistamine drugs will protect liver slices and permit water extrusion and potassium accumulation in circumstances in which the controls will do neither. This has been excellently demonstrated by McLean[4] for slices cut from the liver of vitamin E-deficient rats. This effect is a further complication in work with slices. It may represent protection of the phosphorylating system by inhibitor.

Table 1. EFFECT OF INHIBITORS OF MITOCHONDRIAL 'CONTRACTION' ON PROTEIN PHOSPHORYLATION

Mitochondria isolated in 0·25 M sucrose containing 10^{-3} M versene were swollen by suspension in 0 02 M trihydroxymethylaminomethane hydrochloride, pH 7·2 for 90 min. Mitochondria derived from 500 mgm. liver placed in a system containing 3×10^{-3} M adenosine triphosphate, 3×10^{-3} M manganese chloride and final volume 10 ml. Change ΔE in optical density was observed in optical cells of 1 mm. light-path. Temperature, 20°. For phosphoprotein determination, the method of Schmidt and Thannhauser was adapted for estimation of small amounts of inorganic phosphate liberated from phosphoprotein by alkaline hydrolysis

Mitochondria	ΔE/20 min.	Phosphoprotein–phosphorus (μgm./gm. original liver)	ΔP
Initially swollen	—	1·84	—
Control	0·176	5 24	3·4
2,4-Dinitrophenol (10^{-4})	0 170	4 64	2·8
'Amytal' (10^{-3} M)	0·060	2·7	0·86
Azide (2×10^{-3} M)	0·018	2·20	0 36
Initially swollen	—	3 20	—
Control	0·150	6·00	2·80
'Phenergan' (10^{-4})	0·082	4·40	1 20

It may be argued that phosphoprotein-levels merely reflect adenosine triphosphate-levels, much as in the case of phosphocreatine. Against this view is the fact that there is considerable excess of adenosine triphosphate in the mitochondrial experiments. In the slice, however, such an explanation is more likely, since the levels of adenosine triphosphate and phosphoprotein are of the same order; but there is no evidence from *in vitro* studies with cell-free preparations or slices that 'Phenergan' interferes with adenosine triphosphate synthesis or turnover-rates at the concentrations used.

It is therefore suggested that there is a direct relationship between movement of water and phosphorylation of protein, both in mitochondria and in whole cells. It is also suggested that the reactions regulating these processes are:

$$\text{ATP} + \text{protein} \rightleftarrows \text{ADP} + \text{phosphoprotein} \quad (1)$$

$$\text{ATP} \rightarrow \text{ADP} + \text{inorganic phosphate} \quad (2)$$

$$\text{phosphoprotein} \rightarrow \text{protein} + \text{inorganic phosphate} \quad (3)$$

Table 2. EFFECT OF 'PHENERGAN' ON WATER EXTRUSION, ADENOSINE TRIPHOSPHATE- AND PHOSPHOPROTEIN-LEVELS OF SLICES

Slices about 200 mgm. wet weight were placed in Krebs–Ringer, containing sodium bicarbonate and gassed for first 30 min. with 95 per cent nitrogen–5 per cent carbon dioxide. For aerobic recovery, the gas was 95 per cent oxygen–5 per cent carbon dioxide. Temperature, 38°. Slices were removed from vessels, blotted and weighed, then dried at 105°. For adenosine triphosphate and phosphoprotein determinations, duplicate slices were used, the whole flask contents being deproteinized and homogenized. 'Phenergan' at 10^{-4} *M* was placed in the flasks at the start of aerobic recovery

Slice	Percentage of dry weight Control	 10^{-4} *M* 'Phenergan'	Adenosine triphosphate (μmoles P/gm. wet weight) Control	 10^{-4} *M* 'Phenergan'	Phosphoprotein–phosphorus (μmoles P/gm. wet weight) Control ΔP	 10^{-4} *M* 'Phenergan' ΔP
Initial	28·0	—	1·7	—	1·00	—
30-min. anoxia	21·0	—	0·54	—	0·54	—
30-min. oxygen	22·0	23·0	0·87	0·72	0·76 (0·22)	0·63 (0·09)
60-min. oxygen	24·0	23·0	1·05	1·10	0·80 (0·26)	0·65 (0·11)
90-min. oxygen	25·0	23·0	1·25	1·20	0·76 (0·22)	0·65 (0·11)

All these reactions occur in liver mitochondria and slices. It is to be noted that reaction 2 will degrade phosphoprotein by causing reversal of reaction 1, and that reactions 1 and 3 together can constitute an adenosine triphosphatase. Reactions 2 and 3 will therefore act in concert to catalyse cell degradation under unfavourable conditions. Inhibition of any one of the three reactions will tend to protect. The results so far available suggest reaction 1 as the site of action of the antihistamines, but this itself may be a complex system.

Finally, 'Benadryl' and 'Phenergan' afford potent protection against mitochondrial swelling due to glutathione and much reduce the rate of swelling induced by β-hydroxybutyrate; this again suggests the attractive idea that the single mechanism underlies all these abnormal shifts of water. The importance of the system inhibited by the drugs is illustrated by the fact that they protect rats against liver injury due to thioacetamide[5] and to nutritional deficiency[6], and will also protect mice against murine hepatitis virus[7].

Protection against Liver Injury due to Murine Hepatitis Virus

PREVIOUS work has shown that antihistamine drugs protect against liver injury caused by a variety of agents[1] both in the whole animal and *in vitro*. Judah has also shown that these compounds inhibit mitochondrial swelling *in vitro*, and has indicated a possible mechanism of action[1,2]. McLean[3] has shown that the antihistamine 'Phenergan' will protect rats against nutritional liver necrosis and has demonstrated *in vitro* effects of this drug with slices cut from the livers of rats on necrogenic diets.

In the present communication, it is shown that the antihistamine drug 'Benadryl' affords significant protection to mice infected with murine hepatitis virus (MHV 3) (Dick, Niven and Gledhill[4]). In addition, mouse liver macrophages and parenchymal cells grown in organ culture (Bang and Warwick[5]) were protected by 'Benadryl' from the cytolytic effect of the hepatitis virus.

The murine hepatitis virus was obtained from Dr. Gledhill and inoculated intraperitoneally into adult *C 57/Bl* 6 mice in this laboratory. When these mice became ill, they were killed and their livers made into suspensions as a source of virus inoculum in subsequent experiments. The *LD*50 of virus necessary to cause deaths in the mice within 5 days was established, and it was also found that this dose killed nearly all the animals within 7 days after infection. If 'Benadryl' was administered at the same time as the virus, and a dose of 100 mgm./kgm. body-weight given daily throughout the experiment, a substantial diminution of the number of deaths was found. Table 1 shows the results of this protection experiment. On analysis, it is found that *P* is less than 0·001 even on the seventh day of the experiment, so that protection is highly significant. Subsidiary tests for protection were also used: thus the level of blood malic dehydrogenase was determined at intervals during such experiments (Table 2) and it was found that both 'Benadryl' and 'Phenergan' prevented the marked rise of this enzyme in the serum which is associated with liver injury.

The livers of mice treated with 'Benadryl' and of control mice were also examined histologically. The earliest change is a focal necrosis, clearly seen on the third day, but already present on the second day. This stage is indistinguishable in both groups of mice. However, by the fourth day, the control mice showed confluent areas of necrosis, all liver lobules being affected, and many completely destroyed. In contrast, the mice treated with 'Benadryl' showed very marked preservation of the liver, the lesions still retaining their focal character.

Virus concentration in the livers of treated and control mice was determined on the fourth day after

Table 1. PROTECTION OF MICE AGAINST MOUSE HEPATITIS VIRUS 3. The animals were randomly selected male *C* 57 black mice, weight range 20–22 gm. They were inoculated intraperitoneally with 0·05 ml. of liver suspension and at the same time, where indicated, 'Benadryl' was injected subcutaneously in the appropriate dose

Treatment	No. of animals inoculated	Survivors on day: 5	 6	 7
Control	68	34	21	11
'Benadryl' (100 mgm./kgm.)	61	48	38	26

Table 2. BLOOD SERUM-LEVELS OF MALIC DEHYDROGENASE

Treatment	No. of animals	Malic dehydrogenase, as μmoles DPN reduced/ml. serum/hr.
Controls	4	10·0 (range 7–12)
MHV 3	5	30·0 (range 23–36)
MHV 3, and treated with 'Benadryl'	5	18·0 (range 14–20)

inoculation, when mice in both groups were killed and their livers made into suspensions which were inoculated intraperitoneally, in serial dilutions, into other mice. The results revealed substantially the same concentration of virus in livers from mice treated with 'Benadryl' and control animals, which implies that the effect of the drug was to prevent necrosis of the liver cell, rather than to act directly on the virus. This is in keeping with the hypothesis[2] that the antihistamines inhibit a general mechanism of degradation.

In order to simplify the work, organ cultures of mouse liver on reconstituted collagen were infected with mouse hepatitis virus according to the technique of Bang and Warwick (whose medium was modified to contain 30 per cent of a mixture of calf serum and chick embryo extract in the proportions of 3 : 1). It was found, in keeping with their results, that macrophages are first destroyed by this virus within 24–28 hr. after infection, but that two days later lesions caused by virus also appeared in the hepatic cells, ultimately destroying the entire culture. 'Benadryl' afforded complete protection against injury to both types of cell, in concentrations of 10^{-4}–10^{-6} *M* when added at the same time as the virus. The same protection was observed by the addition of anti-mouse hepatitis virus 6 immune mouse serum, whereas normal mouse serum was without effect.

The presence of hepatitis virus in cultures was determined by inoculation of culture fluids and cells, respectively, into *C57/Bl* 6 mice. Virus was always recovered from control cultures even after several passages through mouse liver organ cultures, but culture fluids from cultures treated with 'Benadryl' showed only minimal amounts of virus. These findings are being further investigated.

It is possible that necrosis of liver cells in an animal infected with hepatitis virus is not directly caused by multiplication of the virus within the cell. 'Benadryl' prevents or delays considerably the necrosis of the cell, but has little or no effect on multiplication of the virus in liver tissue of infected animals. This is supported by the fact that the livers show the same amount of virus present in both groups of animals at the very time that histological and biochemical observations indicate a considerable reduction in the death of cells in the treated animals. This concept may undergo revision in the light of results obtained in organ cultures. However, the results also support the view of a general mechanism of liver injury. This may be taken to involve the system responsible for the maintenance of water and electrolyte balance in the whole cells and possibly the mitochondria, and the inference is supported by the work of McLean and of Judah already cited.

Selective Cytochemical Demonstration of Arginine Groups in Nucleoprotein in the Cell Nucleus

USEFUL information should accrue from cytochemical measurements of the arginine contained in the basic proteins linked to deoxyribonucleic acid in the nucleus. The specific Sakaguchi reaction for arginine has been modified for microspectrophotometry[1].

The main obstacles to its reliable exploitation for the purpose mentioned are: (i) the contribution of arginine groups not involved in the deoxyribonucleic acid–protein complex; (2) the stain in surrounding cytoplasm, necessitating the use of isolated nuclei, with concurrent artefacts; (3) removal of material from the specimen by the strongly alkaline reagent mixture.

We have examined the effect of prior anhydrous benzoylation[2] on this reaction, and the applicability of freeze-drying and freeze-substitution which would minimize some fixation artefacts[3]. Benzoyl chloride reacts at cytoplasmic protein groups but leaves certain nuclear groups unblocked[2,4].

We find that when anhydrous benzoylation (2–3½ hr.) is applied to tissue specimens and is followed by the Sakaguchi procedure[1], the colour reaction of arginine groups is completely prevented in the cell cytoplasm, while a definite nuclear reaction persists. This holds true (with one exception noted later) for all material so far examined, namely, sections or smears from many tissues (and sperm) from rat and mouse, as well as locust testis and root tips of *Vicia* and *Trillium*. Frozen-dried, frozen-substituted and Lewitsky-fixed specimens all give this characteristic effect after benzoylation. Measurements on rat liver made thus will be reported elsewhere[5]. *p*-Nitrobenzoyl chloride[4] produces a similar result.

A complication in the interpretation of the results of the normal Sakaguchi method itself is shown by our further observation that frozen-dried or frozen-substituted tissues, fixed in sections or smears by absolute ethanol and treated by the Sakaguchi method alone, show in general no nuclear reaction, either by eye or two-wave-length spectrophotometry, except in the sperm head. A normal reaction is seen in the cytoplasm. This is in contrast to the relatively strong nuclear reaction found after various chemical fixatives, for example, in Lewitsky's fluid, and raises the question of diffusion artefacts in the fixation and reaction. This has been examined by interference microscope measurements of the changes in dry mass of cell nuclei exposed to the Sakaguchi reaction mixture, after various initial treatments. The results (Table 1) show that the negative nuclear reaction in frozen-dried or frozen-substituted specimens is due to a very considerable removal of nuclear material in the strongly alkaline medium. This is largely extracted into the medium, although some may be adsorbed and contribute to the observed cytoplasmic reaction for arginine. Coating the specimen with 'Celloidin' does not prevent this loss. The extraction can be prevented either by benzoylation or, in part, by treatment with Lewitsky's fluid (Table 1). In the latter case there is an apparent greater retention after 'Celloidin' coating[4], although re-distribution of dissolved material under the 'Celloidin' film must then be a possible source of error. Results very similar to those in Table 1 have also been obtained on frozen-dried tissue sections (with and without benzoylation).

Table 1. CHANGES IN DRY MASS OF INDIVIDUAL CELL NUCLEI AFTER EXPOSURE TO SAKAGUCHI REACTION MEDIUM

Treatment*	Material†	No. of samples	No. of nuclei	Dry mass‡ of nucleus after exposure§ (per cent)
None	Mouse kidney	2	‖	<10
	Mouse liver	2		<10
	Rat liver	2		<10
	Mouse sperm heads	1	6	100
Benzoylated (2½–3 hr.)	Mouse kidney	1	6	95
	Mouse liver	3	12	99
	Rat liver	1	5	103
	Mouse sperm heads	1	3	105
Lewitsky (ref. 1)	Mouse kidney	3	10	63
	Mouse liver	1	3	40¶
	Mouse sperm heads	1	8	100
Lewitsky ('Celloidin' coated) (ref. 1)	Mouse kidney	1	6	76
	Rat liver	1	8	91

* All smears were initially frozen-substituted in methanol (minimum 24 hr.), then fixed in ethanol for ½–1 hr. (Extension of fixation to 24 hr. does not change the behaviour.)

† Smears containing whole cells and whole nuclei. Homogeneous nuclei of regular geometry were selected for measurement.

‡ Measured using Baker interference microscope, with half-shade eye-piece and × 100 shearing objective. Corrected for any change in measured area of nucleus. The same nucleus was measured in each case, in water, before and after treatment, and the final value expressed as percentage of the initial value. No significance is attached to changes of less than 10 per cent. (Means for all nuclei are recorded.)

§ Medium is 0·6 per cent sodium hydroxide (30 ml.) + 1·2 per cent sodium hypochlorite (1·2 ml.) + 70 per cent ethanol (1 ml.). Exposed 3 min., then washed with water.

‖ Exact measurements could not be performed here after exposure; all nuclei in the field were swollen and of extremely low dry mass. 'Celloidin'-coated samples gave the same results.

¶ Approximate only, due to considerable swelling.

These observations lead us to conclude:

(1) Benzoyl chloride, in the anhydrous medium, reacts at the guanidino groups of arginine (cf. ref. 7 for a similar benzoylation of arginine side-chains in isolated proteins). This reaction proceeds in the proteins in the cell cytoplasm, and probably in some nuclear proteins; but a certain fraction of nuclear protein arginine is unable to react with this reagent. This fraction alone is revealed by the subsequent Sakaguchi reaction which cannot proceed at acylated guanidino groups. The most probable reason for the non-availability of this nuclear arginine fraction is that these are the arginine side-chains considered to be bound in salt linkage[8] to deoxyribonucleic acid phosphate groups. It is presumed that these arginine side-chains, in contrast to those in other situations, are held in the charged form even in the anhydrous pyridine–acetonitrile medium and so cannot be acylated. However, all types of arginine side-chains are reactive in the Sakaguchi method due to discharge in the aqueous alkali which must (for this same reason) be employed.

Further evidence for the above interpretation is that, while the reaction is in general confined to the cell nucleus and, in fact, virtually to the chromosomes in dividing cells, a cytoplasmic reaction is also found in one case, namely, where a high accumulation of ribonucleoprotein is present, that is, in the basal strongly basophilic region of active pancreatic acinar cells (in contrast to the negative cytoplasm of neighbouring cells of other types), and also in certain plant root meristem cells. Presumably salt-linked arginine groups are present there, too. The blocking reaction is not sensitive to prior water treatment, as it is in the case of histidine groups[3,4], again consistent with a stable salt linkage. Prolonged benzoylation (18 hr.) does not abolish the reaction, that is, a merely kinetic difference is not involved.

(2) While it is preferable to employ freeze-drying or freeze-substitution, to avoid initial diffusion errors, these processes (followed by ethanol fixation) leave the nucleoprotein soluble in the alkaline medium, and this must be countered by treatment of the type described. Benzoyl chloride is presumably effective in this instance due to the insolubilizing effect of benzoyl groups introduced at other sites in the nucleoprotein (an effect we have confirmed on isolated calf thymus histone). Even after such treatment, the possibility of diffusion errors, below the limits of total mass measurements by interferometry of the present type, remains in the Sakaguchi method.

(3) The method described can be applied to tissue specimens without isolation of nuclei, for the microspectrophotometric measurement of the nuclear arginine fraction in question. Measurements to support and extend these observations will be reported elsewhere[5].

The plant material used was kindly supplied by Dr. J. Chayen and Mr. L. F. LaCour.

Reversible Dissociation of Ribonucleic Acid

THE work reported here was prompted by the observation that when infectious ribonucleic acid, isolated from Ehrlich ascites cells infected with Mengo encephalomyelitis virus[1], was incubated with crystalline bovine plasma albumin in solutions of physiological ionic strength, its biological activity was lost or sharply inhibited. No loss of infectivity was observed when mixtures of these two substances were incubated in concentrated solutions of sodium chloride (0·6–1·0 *M*). However, infectivity was not regained when protein–ribonucleic acid mixtures in physiological saline were made 0·64 *M* with respect to sodium chloride. The biological activity of the Mengo ribonucleic acid and of the Mengo ribonucleic acid–bovine plasma albumin mixtures was assayed by a plaque method employing monolayers of Earle's *L* strain mouse fibroblasts[2].

The ribonucleic acid used in the experiments described here was isolated from Ehrlich ascites tumour cells by the phenol method previously described[3]. The fraction of high molecular weight was separated from material of low molecular weight by precipitation in 1 *M* sodium chloride. In the analytical ultracentrifuge this fraction showed two peaks with sedimentation velocities of 16–18 S. and 32–34 S., respectively, the component sedimenting

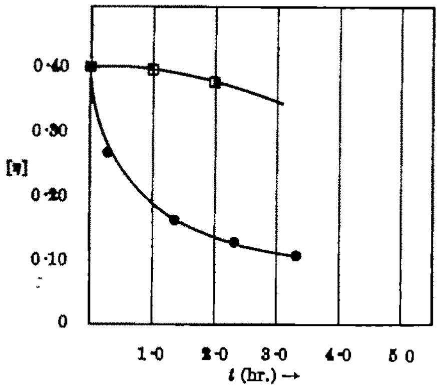

Fig. 1. Intrinsic viscosity of ribonucleic acid (1·2 mgm./ml.), —□—; and of a ribonucleic acid (1·2 mgm./ml.)–α-lactalbumin (5 mgm./ml.) mixture, —○— in physiological saline

more rapidly comprising 60–65 per cent of the total. All ultracentrifugal analyses were performed in the 'Spinco' model *E* ultracentrifuge, using either schlieren optics or ultra-violet absorption and the 'Analytrol' with the microanalyser attachment[4].

The interaction of ribonucleic acid with three different proteins, namely, bovine plasma albumin, bovine γ-globulin, and α-lactalbumin (kindly supplied by D. Martin Kronman, Eastern Regional Laboratories, United States Department of Agriculture) has been studied. Under the proper conditions, the admixture of protein and ribonucleic acid in solutions of physiological ionic strength results in the conversion of the 16 S. and 32 S. components or ribonucleic acid into components sedimenting more slowly. Since these changes in sedimentation properties are accompanied by a decrease in the viscosity and turbidity of the solutions, it seems reasonable to assume that they reflect a dissociation of the ribonucleic acid. The degree of dissociation depends on the protein used, the ratio of protein to ribonucleic acid concentration, and the absolute concentrations of each. The dissociation can be partially or completely reversed by making the solution 1 *M* with respect to sodium chloride or 0·01 *M* in magnesium sulphate. Neither the conversion of ribonucleic acid into slowly sedimenting components in physiological saline solution nor the regeneration of the rapidly sedimenting components occurs rapidly. At 4° C., 2–4 hr. are required for the first process, and a somewhat longer period is required for the second.

At concentrations of ribonucleic acid greater than 1 mgm./ml., bovine plasma albumin did not affect the sedimentation velocity of the nucleic acid. However, in a solution containing 20 and 400 μgm./ml. of ribonucleic acid and bovine plasma albumin, respectively, most of the nucleic acid was found to sediment with the bovine plasma albumin peak. The sedimentation constant of the latter increased from 4·3 to 5·1–5·3 S. The rapidly sedimenting components of ribonucleic acid were regained when the solution was made 1 *M* with respect to sodium chloride, or 0·01 *M* with respect to magnesium sulphate.

α-Lactalbumin is a protein with a molecular weight of 15–17,000 and a sedimentation constant of 1·6 S. Because of its small size, it is particularly well suited for studies of ribonucleic acid–protein interaction. Fig. 1 shows the changes in the intrinsic viscosity of a ribonucleic acid solution (1·2 mgm./ml.) when incubated with α-lactalbumin (5 mgm./ml.). Although incubation of the ribonucleic acid alone produced a decrease in the viscosity of the solution, it was slight compared with the very rapid decrease which resulted from addition of protein. In a similar mixture, incubated for 12 hr. at 4° C., a new peak with a sedimentation constant of 3·0 S. appeared. The addition of sodium chloride only partially reversed the dissociation.

It was possible to dissociate ribonucleic acid by means of bovine γ-globulin at all concentrations of ribonucleic acid and protein. The degree of dissociation depended on the ratio of protein to ribonucleic acid. At high ratios there was complete dissociation, and all the ribonucleic acid travelled with the protein peak in the ultracentrifuge. At lower ratios there was less dissociation. It was possible to reverse the dissociation in mixtures containing low concentrations of ribonucleic acid and a low ratio of protein to ribonucleic acid, while only partial reversal was obtained under other conditions.

In Fig. 2, the distribution of sedimentation constants observed by means of ultra-violet optics in a mixture containing 50 μgm./ml. bovine γ-globulin and 25 μgm./ml. ribonucleic acid is presented. The distribution shown in Fig. 2*A* was obtained after the mixture had stood for 2 hr. in 0·14 *M* sodium chloride, buffered at *p*H 7·0 with phosphate of ionic strength 0·01. At that time, an aliquot was made 0·01 *M* with respect to magnesium sulphate. The distribution in Fig. 2*B* was obtained with the latter aliquot 3 hr. after the addition of magnesium salt. Since the protein contributed only about 5 per cent of the optical density, the distributions are essentially those of the ribonucleic acid.

Our results suggest that ribonucleic acid exists in dynamic equilibrium with sub-units, and that the equilibrium is shifted towards dissociation by binding of the sub-units by protein. If this is true, it should be possible to demonstrate such an equilibrium without the use of protein. A partial separation of the 16–18 S. component in the ultracentrifuge by means of a partition cell[4] did give fractions the sedimentation properties of which changed with time so as to approach those of the original solution. The fractions were unstable and regenerated the high molecular weight (32 S.) peak only if fractionation had been inefficient.

One may sum up these findings by saying that the dissociation of ribonucleic acid is a reversible process if it is not carried too far. If it is assumed that the irreversible dissociation does not involve degradation,

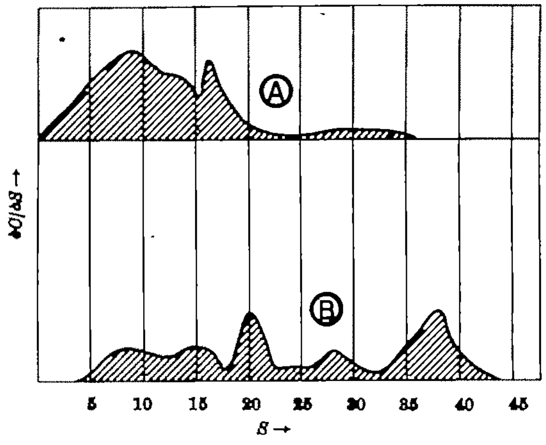

Fig. 2. Sedimentation distribution of two mixtures containing 50 μgm./ml. bovine γ-globulin and 25 μgm./ml. ribonucleic acid: (*A*) 3 hr. after mixing in physiological saline; (*B*) 6 hr. after mixing and 3 hr. after making the mixture 0·01 *M* with respect to magnesium ions

but rather a failure to re-assemble the molecule in a specific order by random processes, the measured sedimentation constant of 3·0 S. and intrinsic viscosity of 0·1 (Fig. 1) obtained with a mixture of ribonucleic acid and α-lactalbumin may be used to estimate the probable sub-unit size at 35–75 nucleotides. Considering only the reversible dissociation seen with bovine γ-globulin and bovine plasma albumin, the sedimentation results (Fig. 2) can be employed to estimate an upper limit of 200 nucleotides for the sub-unit size.

The results of Loring *et al.*[5] would suggest that the ribonucleic acid of tobacco mosaic virus is capable of reversible dissociation into sub-units, with retention of potential biological activity. The recovery of infectivity implies a specific re-assemblage of the ribonucleic acid molecules.

Carbohydrates of *Ecklonia radiata*

In connexion with our work on the chemistry of cellulose and related carbohydrates, it was found desirable to investigate certain properties of algal polysaccharides. In seeking a source of these materials we noted that Australian species of brown algæ appear to have received little chemical study, although the carbohydrates of *Ecklonia maxima*, *Laminaria pallida* and *Bifurcaria brassicaeformis* of South Africa have been investigated[1]. The northern hemisphere species, especially of the genus *Laminaria*, have been studied in considerable detail[2,3]: large seasonal variations occur in the contents of laminarin (0–30 per cent), alginic acid (10–30 per cent) and mannitol (0–30 per cent); the fucoidin content is low and less variable[3,4].

Recently we have made a preliminary study of the carbohydrate components of *Ecklonia radiata* (Ag.) J. Ag., which occurs in the sub-littoral zone of the southern coasts of Australia. Fresh whole seaweed, collected in autumn at Point Lonsdale, Victoria, was milled through breaker plates in a Bauer defibrator and the carbohydrates were extracted from the milled material with 1 per cent hydrochloric acid by a two-stage steeping treatment, essentially as described by Black *et al.*[5]. On allowing the solution to stand for several days, little or no insoluble laminarin was precipitated. One fraction (I) of polysaccharides was precipitated by the addition of ethanol to a concentration of 74 per cent, another (II) by further addition of ethanol to the supernatant to a final concentration of 85 per cent. The polysaccharides (I + II) were obtained in a yield of about 6 per cent by redissolving the precipitates in a small amount of water and triturating with ethanol and ether. Fraction I consisted of laminarin and fucoidin; fraction II almost entirely of laminarin. Fractional precipitation of I with ethanol gave only a partial separation of the soluble laminarin and fucoidin. However, part of the fucoidin could be removed on an anion-exchange resin (a similar method has been used by Unrau, A., and Smith, F.; personal communication), 'Duolite *A*4', after first passing the solution through 'Amberlite *IR*-120(H)' to remove calcium and other cations. A more satisfactory separation was achieved by treatment with cetyl trimethylammonium bromide. The polysaccharides were identified by infra-red spectroscopy and the components of their acid hydrolysates by chromatography, in some cases combined with infra-red examination of sugars eluted from chromatograms and freeze-dried.

Further work was done with samples collected in summer. Mannitol was extracted with butanol[1], and crystallized from butanol and from ethanol; it was characterized by chromatography, physical constants and infra-red spectroscopy. Alginic acid was obtained by alkaline extraction of plant material from which other carbohydrates had been removed. It was isolated as the free acid and sodium salt, which were compared with authentic samples. Analyses were carried out according to the methods developed by Cameron, Ross and Percival[6]. The average contents for December–January were found to be as follows:

	Laminae	Midrib*
Mannitol (per cent)	16	13
Alginic acid (per cent)	20	26
Laminarin (per cent)	5·4	1·8
Fucoidin (per cent)	1·0	1·2

* The 'midrib' is that portion of the frond, comprising the elongation of the stipe, from which the 'laminae' have been removed.

The seasonal variation in the content of the four carbohydrates is of interest in connexion with their biochemical function and possible utilization. This aspect of the work and others are receiving attention, and will be reported elsewhere. We wish to thank Miss S. Austin, Mr. K. J. Harrington and Mr. G. Davies for help with this work.

Fatty Acid Composition of the Lipids of Pasture Grasses

Little information is available on the total fatty acid composition of pasture grass lipids. Shorland[1,2] reported that the fatty acids of the acetone-soluble lipids of cocksfoot grass and of rye grass grown in New Zealand comprised about 3 per cent of the dry matter of the grass; ester-fractionation analysis showed that saturated acids (mostly palmitic) accounted for less than 20 per cent of the total acids and that the remaining unsaturated acids consisted largely of linoleic and linolenic acids. Details were not given of the analysis of the fatty acids of the acetone-insoluble lipids (phospholipids), though it was stated[1] that those from cocksfoot grass resembled the fatty acids of the corresponding acetone-soluble lipids, except for a somewhat lower mean unsaturation of the C_{18} unsaturated components. In earlier work Smith and Chibnall[3] isolated the phospholipid fatty acids of cocksfoot grass and showed that they consisted mainly of linoleic, linolenic and saturated components. Contrary to the assumption hitherto made that the acetone-soluble lipids of forage grasses are mainly triglycerides, plus unsaponifiable matter, Weenink[4] has recently shown that about 60 per cent of this lipid fraction of New Zealand grasses consists of galactosyl glyceryl esters of fatty acids, largely linolenic acid.

As part of investigations on the fate of dietary lipids in the rumen of the sheep a detailed analysis was made of the total fatty acids of artificially dried milled grass containing about 50 per cent of perennial ryegrass, 25 per cent of cocksfoot, 15 per cent of timothy grass and 10 per cent of Italian ryegrass grown in Aberdeenshire and cut in July 1959. The material was exhaustively extracted successively with hot 95 per cent ethanol and hot chloroform–methanol (2 : 1 by vol.). The lipids in each extract were hydrolysed with ethanolic potassium hydroxide, unsaponifiable matter was removed and the fatty acids were recovered. The fatty acids obtained from the ethanolic extract and from the chloroform–methanol extract, respectively, represented 2·02 and 0·27 per cent of the dried grass and hence 88·2 and 11·8 per cent of the total fatty acids.

Each group of fatty acids was converted to methyl esters for analysis by gas chromatography, employing polymerized ethylene glycol succinate (prepared as for the adipate[5]) as liquid phase at 170° C. and argon as carrier gas. In Table 1 is shown the composition of each group of acids and the resultant composition of the total fatty acids of the grass lipids.

Table 1. FATTY ACID COMPOSITION OF PASTURE GRASS LIPIDS
(Values as percentage by weight of total acids in each group)

Acid	Source of fatty acids		Total fatty acids
	Lipids extracted with ethanol	Lipids extracted with chloroform–methanol	
Myristic	1·2	0·8	1·1
Palmitic	14·4	26·8	15·9
Palmitoleic	2·5	2·6	2·5
Stearic	1 7	4·4	2·0
Oleic	3·2	5·1	3·4
Linoleic	12·8	15·4	13·2
Linolenic	64·2	39·6	61·3
Arachidic	—	2·1	0·2
Behenic	—	3·2	0 3

The two groups of fatty acids contributing to the total acids are broadly similar in composition, though the lipids of the chloroform–methanol extract contain relatively more palmitic acid and less linolenic acid than the lipids of the ethanol extract and, in addition, are characterized by the presence of small amounts of arachidic and behenic acids. The total fatty acid composition resembles closely that of the leaf lipids of maize[6] (another graminaceous plant) and also that of the lipids of clover-rich pasture[7]. Linolenic acid is the outstanding component, and the unsaturated C_{18} acids together make up more than 75 per cent of the total acids; of the saturated fatty acids present, palmitic acid predominates.

The lipids in each of the two extracts of the dried grass were subjected to a preliminary fractionation. The ethanol-soluble lipids were subjected to chromatography on silicic acid (cf. Garton and Duncan[8]); a fraction eluted with 5 per cent ether in light petroleum contained free fatty acids and neutral lipid. The free acids were isolated and found to comprise 13·5 per cent of the total fatty acids of the grass; their composition is shown in Table 2. Following saponification and removal of unsaponifiable matter, fatty acids accounted for 92 per cent of the remaining neutral lipid, which was thus taken to be triglyceride. These fatty acids represented only 3·3 per cent of the total fatty acids of the grass. Subsequent elution with 10 per cent methanol in ether removed lipid corresponding to 62 per cent of the ethanol-soluble lipids. This fraction apparently consists of galactosyl glyceryl esters as described by Weenink[4]; hydrolysis gave glycerol, galactose and fatty acids, of which linolenic acid accounted for 82·0 per cent (Table 2).

Table 2. FATTY ACID COMPOSITION OF FRACTIONS DERIVED FROM THE ETHANOL-SOLUBLE LIPIDS
(Values as percentage by weight of total acids in each group)

Acid		Source of fatty acids	
	Free fatty acids	Triglycerides	Fraction eluted with 10 per cent methanol in ether
Myristic	1·6	3·3	0 2
Palmitic	13·0	14·6	7·0
Palmitoleic	2·4	1·8	1·6
Stearic	1·6	2·9	1·5
Oleic	4·3	8·1	1·8
Linoleic	17·4	23·1	5·9
Linolenic	59·7	46·2	82 0

The lipids extracted with chloroform–methanol were separated into acetone-soluble and acetone-insoluble (phospholipid) portions. Of the total fatty acids in the lipids in the chloroform–methanol extract, 30 per cent (including almost all the arachidic acid and behenic acid) were present in the acetone-insoluble portion; the acetone-soluble lipids were relatively richer in linolenic acid than the acetone-insoluble lipids.

Further work on the nature of the lipids of grasses and other animal feeds is in progress.

PHYSIOLOGY

A Biological Interval Analyser

A FREQUENT requirement in the analysis of biological data is the classification of time-intervals. Thus one might wish to know the most probable interval between heart-beats, or the most probable reaction time of forefinger movements in response to sound. The usual way of acquiring this sort of information is by manual measurements of relatively long biological records. This method, however, can

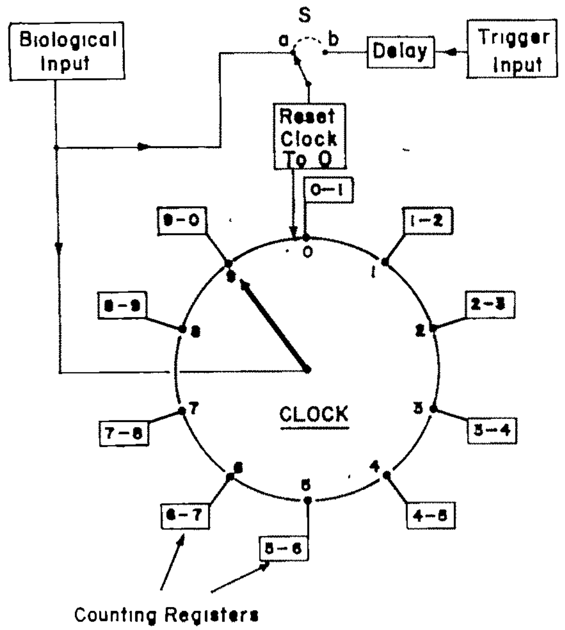

Fig. 1

become extremely time-consuming when the number of biological signals to be classified is large. An example may serve to illustrate our point. The neurons of the unanæsthetized, unstimulated cat's brain are in a state of continual 'spontaneous' activity. Their mean frequency of discharge per minute is constant (some 5–20/sec.) when observed over long periods of time, but it appears impossible to predict with certainty the exact time at which the next action potential in a series will occur. Cells in the resting visual cortex are also engaged in continual activity, but will respond to a flash of light focused upon the retina with an increased probability of discharge. One can state the relationship between stimulus and response in these circumstances only in terms of probability, since any particular flash of an identical series may or may not be followed by an action potential.

There are, thus, two questions one might reasonably ask about the behaviour of cells in the unanæsthetized cerebral cortex. (1) Is the resting discharge of the neurons random with respect to time? (2) What is the probability that an action potential will occur within a specified interval of time after the stimulation? The manual analysis of two minutes of record from cortical units may involve the measurement and classification of some 1,200 intervals and can occupy one full man-day. For this reason we have designed and built an electronic interval analyser which provides an instantaneous display of the completed analysis.

A functional diagram of this device is shown in the accompanying figure. The central component is a clock which connects the biological input in succession to each of ten digital counting registers. Suppose that we require to know the distribution of intervals between discharges of a single neuron in the 'resting' brain. The rate of revolution of the clock is first pre-set to a convenient value so that the biological signals are fed to each of the counting registers for, say, 100 m.sec. The switch S is set to position a. The first action potential causes the clock to jump from its resting position 9, to position 0, where in the absence of another action potential it rests for 100 m.sec. and then jumps to position 1. If the next action potential arrives during the next 100 m.sec., the event is recorded in counting register 1–2 and the clock is reset simultaneously to position 0. In this way, the intervals between successive action potentials are measured and classified. All intervals between action potentials that are greater than 9 × 100 m.sec. will be accumulated in register 9–0. At the end of a series of action potentials the counting registers of the instrument display numbers proportional to the probabilities of occurrence of various intervals between action potentials.

Another mode of operation of the analyser provides the probabilities that action potentials will occur at various times after the stimulation. For this operation the switch S is turned to b, when initiation of the clock-cycle is triggered by a pulse synchronous with stimulation. Suppose that the clock's rotation is pre-set so that it spends 20 m.sec. in each position. Suppose also that the frequency of repetition of a stimulus is 1 per sec. The first stimulus of a series will move the clock from position 9 to position 0 and initiate its stepwise progress. Should an action potential occur during the 20 m.sec. that the clock rests on position 2, then the event will be stored in register 2–3. The clock is not reset by this action potential, but continues to move consecutively through positions 3–9, distributing action potentials to the appropriate registers. Once the clock attains position 9 it waits there until the next stimulus begins the cycle again. At the end of the analysis, counts appear in the registers which are proportional to the probabilities of response 0–20, 20–40 . . . 160–180, 180–1,000 m.sec. after the stimulus. By use of the variable delay indicated in the figure, it is equally easy to obtain probabilities of response 180–200, 200–220, . . . m.sec. after the stimulation.

Although this instrument was specifically designed for the analysis of the behaviour of central neurons, its use is clearly not limited to this function. The same instrument could, for example, be employed with equal ease to make similar analyses of cardiac rhythm, respiratory activity, or animal behaviour in conditioning experiments.

Depressing Activity of Meprobamate on the Reticulo-Endothelial System

Data in the literature point to tranquillizers as drugs having a certain influence on the responsiveness to infections. Patients treated with reserpine or chlorpromazine have decreased resistance to infectious diseases[1,2].

Chlorpromazine increases susceptibility of mice to infection with *Salmonella enteritidis*[3] and depresses the phagocytic activity of the reticulo-endothelial system[4]. The production of anti-*Salmonella typhimurium* agglutinins in rabbits is decreased by meprobamate[5]. Vinegar and Berger[6] found that the clearance-rate of carbon particles in blood of mice is depressed 24 hr. after the administration of a single high dose of certain tranquillizers. Meprobamate at two dose-levels (100 and 200 mgm./kgm.) does not affect clearing. They attributed the depression of the reticulo-endothelial system as due to the liberation of corticosteroids from the adrenal cortex caused by the tranquillizers. It is known in fact that corticosteroids inhibit the clearing of carbon particles by the reticulo-endothelial system[7,8] and that chlorpromazine induces adrenocorticotrophic hormone release from the hypophysis[9] and hypertrophy of the adrenal cortex[10]. On the other hand, adrenalectomy has been reported as a condition which does not affect clearing[8,11] and that the depression of the reticulo-endothelial system does not appear in adrenalectomized hydoxyzine-treated mice[6]. It seemed, therefore, of some interest to investigate the influence of meprobamate, given in therapeutical doses and for more than one single administration, on the reticulo-endothelial system and to have more evidence for supporting the theory of the interference of the adrenal cortex.

Adrenalectomized (14)	—	7·2 ± 0·57*	55′ ± 6·18*	2·72 ± 0·18*

Number of animals in parentheses. * $P < 0·001$; † $0·001 < P < 0·005$; ‡ $0·01 < P < 0·02$; § N.S.

Male Rockland-Swiss mice weighing 20 gm. were divided into three groups; one served as control and received saline, another was given subcutaneously 25 mgm./kgm. of meprobamate and another was adrenalectomized. Clearance of carbon particles was carried out as described by Heller *et al.*[12], and determined in the meprobamate-treated group after 3, 7 and 15 days of treatment, and in the adrenalectomized group after 7 days in the surviving animals. For each animal was then calculated: the phagocytic index (K), that is, the constant of the equation of disappearance of carbon from blood, the half-time of carbon disappearance ($T/2$) and the corrected phagocytic index (α), which measures the phagocytic activity per unit weight of liver and spleen. The results are summarized in Table 1. From the results it appears that the activity of the reticulo-endothelial system is strongly depressed at the beginning of the treatment with meprobamate, returns almost to normal after 7 days and is again depressed after 15 days. Our results for the effects of adrenalectomy do not agree with those of other authors and do not allow the possibility of investigating the effects of meprobamate on the adrenalectomized animals. So far as the mechanism by which meprobamate affects the reticulo-endothelial system is concerned, it may be supposed that the tranquillizer induces at the beginning a 'block' of the adrenal cortex function (depression of clearing) which returns to normal in a few days (almost normal clearing); the continuous administration of the tranquillizer leads later on to an increased secretion of adrenal corticoids which may explain the depressed activity of the reticulo-endothelial system after 15 days of treatment.

Anti-Fertility Action of a Monoamine Oxidase Inhibitor

An earlier communication has directed attention to the anti-inflammatory properties of inhibitors of monoamine oxidase[1]. Similar properties for iproniazid, one such substance, have been described independently[2]. The similarities between the vascular events of implantation of the fertilized ovum and of the inflammatory reaction, together with the low toxicity of certain monoamine oxidase inhibitors, prompted the trial of these compounds as orally administered inhibitors of conception. The work was also stimulated by reports of the effect of 5-hydroxytryptamine and iproniazid in terminating pregnancy in mice[3].

Female albino rats of the Wistar strain, weighing 150–250 gm., were caged with similar male rats (one male to every five or six females) for a mating period of 9 days, the males then being removed. Animals receiving the monoamine oxidase inhibitor did so in their drinking water. The drug used was (1-methyl-2-phenoxyethyl)hydrazinium (compound *HP*1275) obtained from Smith and Nephew Research, Ltd. The dosage ranged from 0·1 to 0·5 mgm. per ml. of drinking water. The nature of the experiment meant that both female and male rats received the drug throughout the period of mating. The females were, however, put on the drug 24 hr. before the males were added to their cage.

Table 1 shows that the higher dose led to complete suppression of fertility. Both female and male rats on this regime showed no obvious abnormality or disturbance of health. The lower dose-levels showed less-striking effects.

Table 1. EFFECT OF COMPOUND *HP*1275 ON THE INCIDENCE OF PREGNANCY IN RATS AND MICE

Concentration of *HP*1275 in drinking water (mgm./ml.)	Animal	Approximate dose (mgm./kgm./24 hr.)	No. of females	No. of females pregnant	Pregnant (per cent)
None	Rat	None	48	24	50
0·5	Rat	25	48	0	0
0·25	Rat	12	20	4	20
0·10	Rat	5	20	8	40
None	Mouse	None	48	9	19
0·5	Mouse	25	48	3	6

A similar experiment was conducted with mice, using a four-day mating period in which both males and females received 0·5 mgm./ml. of compound *HP*1275 in their drinking water. The results here were less impressive although the incidence of pregnancy was reduced. Female rats which had received 0·5 mgm./ml. of *HP*1275, when mated three weeks later without the addition of the drug to their drinking water, conceived normally. Of 24 females so treated, 11 became pregnant and delivered normal litters which survived.

Although the effect in rats was striking, interpretation is difficult. It is not certain whether the action of the drug is on the female or partly or wholly on the male. It has not yet been possible to devise an experiment in which animals of only one sex received the drug and yet in which there was an adequate mating period with minimal handling of the animals. However, other results indicate that the action is probably on the female[3].

Compound *HP*1275 has been administered to male and female rats for several months in doses up to 50 mgm./kgm./24 hr. without detectable clinical or histologicl aabnormalities. A general toxic basis for the anti-fertility effect of the drug is therefore rather less likely than a more specific action. However, it cannot be said to be established that the drug acts by inhibition of monoamine oxidase.
